C. M. Larson, B. S., Chief Consulting Engineer, Sinclair Refining Company. *Lubricants.*

John M. Lessells, B. Sc., Associate Professor of Mechanical Engineering, Massachusetts Institute of Technology. *Machine Elements.*

H. J. Macintire, Professor of Refrigeration, University of Illinois. *Mechanical Refrigeration.*

Douglas C. MacMillan, B. S., Marine Engineer, George G. Sharp, Naval Architect. *Testing and Trials of Machinery.*

W. H. McAdams, M. S., Professor of Chemical Engineering, Massachusetts Institute of Technology. *Heat Transmission by Conduction and Convection.*

L. S. McCready, Commander USMS. Head, Department of Engineering, U. S. Merchant Marine Academy. *Deck Machinery.*

E. Bryce McCrohan, Jr., M. E., Senior Naval Architect, U. S. Navy Yard, New York. *Naval Architecture.*

Jerome B. McMahon, B. S., Manager of Controller Division, The Foxboro Company. *Automatic Control.*

Lionel S. Marks, B. Sc., M. M. E., Professor of Mechanical Engineering, Harvard University. *Strength of Wood.*

F. H. Norton, B. S., Associate Professor of Ceramics, Massachusetts Institute of Technology. *Refractories.*

George A. Orrock (deceased), M. E., Consulting Engineer. *Condensation.*

R. E. Peterson, M. S., Manager Mechanics Department, Westinghouse Research Laboratories. *Machine Elements.*

B. R. Queneau, Ph. D., Assistant Professor of Metallurgy, Columbia University. *Iron and Steel.*

H. S. Rawdon, B. Ch. E., Chief of the Division of Metallurgy, National Bureau of Standards. *Corrosion.*

Odin Roberts, S. B., A. M., LL. B. (deceased), Counsellor at law. *Patents for Inventions.*

Ernest W. Schoder, B. S., Ph. D., Professor of Experimental Hydraulics, Cornell University. *Hydraulics.*

David M. Schoenfeld, Assistant Manager, Marine Department, Combustion Engineering Company, Inc. *Boilers and Fuels.*

W. H. Shipman, Plant Engineer, The Babcock & Wilcox Company. *Pipe Line Flexure Stresses.*

Cyril S. Smith, Sc. D., Research Metallurgist, American Brass Company. *Nonferrous Metals.*

Frank V. Smith, Federal and Marine Divisions, General Electric Company. *Electric Ship Propulsion.*

William Spraragon, B. E., Technical Secretary and Editor, American Welding Society. *Welding.*

Abraham Thaelor, Assistant Chief Engineer, Federal Shipbuilding and Dry Dock Company. *Heating, Ventilating and Air Conditioning.*

F. C. Thorn, Ch., Chief Chemist, The Garlock Packing Company. *Packings.*

Brackett K. Thorogood, Formerly Instructor in Mechanical Engineering, Harvard University. *Mechanism.*

S. Timoshenko, Professor of Theoretical and Applied Mechanics, Stanford University. *Vibration Problems.*

W. Turnwald, Nordberg Manufacturing Company. *The Steam Engine.*

George L. Tuve, M. E., Professor of Heat-power Engineering, Case School of Applied Science. *Mechanical Measurements.*

G. A. Ungar, M. E., Consulting Engineer, Formerly Chief Engineer, S. K. F. Ball Bearing Company. *Bearings with Rolling Contact.*

Hermann von Schrenk, A. M., Ph. D., Consulting Timber Engineer. *Wood.*

R. W. Vose, B. S., M. S., Director of Research, Chicopee Manufacturing Corp., formerly Instructor in Applied Mechanics, Harvard University. *Mechanical Properties of Materials.*

A. M. Wahl, Ph. D., Research Engineer, Mechanics Department, Westinghouse Research Laboratories. *Machine Elements.*

Harold C. Weber, D. Sc., Associate Professor of Chemical Engineering, Massachusetts Institute of Technology. *Thermal Properties of Bodies and Thermodynamics.*

Llewellyn Williams, Vice President in Charge of Engineering and Manufacturing, The York Corporation. *Cargo Refrigeration.*

PREFACE

This handbook is compiled especially for the use of design engineers and technical students. Operating engineers, it is hoped, will find it useful also for its presentation of design and construction details, though no attempt has been made to include instructions covering the adjustment and maintenance of marine propulsion machinery.

This book is designed by the publishers to be a successor to "Marine Engineers' Handbook," edited by the late Commander Frank W. Sterling, published in 1920, and available until recently. In attempting a revision to provide material representative of current practice, it was found that, because of virtually complete obsolescence, an entirely new book instead of a revision was in order. Commander Sterling's book was the Bible of a generation of marine engineers; it is hoped that this volume as a successor may be equally well received.

The book retains practically as originally presented the section on Reciprocating Steam Engines but all other sections on special marine engineering topics are completely new. Much material that is of pertinent value to the marine engineer has been reprinted from the fourth edition of the "Mechanical Engineers' Handbook" with the kind permission and full cooperation of Professor Lionel S. Marks.

It is the sincere belief of the editor that the book is up to date and that it incorporates all the sound and proved marine engineering practice that has been developed rapidly within the past several years. The editor has been fortunate in having the aid as contributors of many men who have been closely associated with important current developments in this field of engineering and takes this opportunity of thanking them for their prompt and painstaking work.

In so extensive a compilation there will undoubtedly be inadvertent mistakes and omissions. The editor will be thankful if comments and constructive suggestions are communicated to him through the publishers.

J. M. LABBERTON.

NEW YORK, N. Y.,
September, 1945.

CONTENTS

For the detailed contents of any section consult the title page of that section. For the alphabetical index see pp. 1953 to 2013.

SYMBOLS AND ABBREVIATIONS

For symbols of chemical elements, see p. 530; for electric and magnetic symbols, see pp. 1688 and 1701; for abbreviations applying to metric weights and measures, see p. 72.

Pairs of parentheses, brackets, etc., are frequently used in this work to indicate corresponding values. For example, the statement that "the cost per kw of a 30,000-kw plant is $53; of a 15,000-kw plant, $62; and of an 8000-kw plant, $72," is condensed as follows: The cost per kw of a 30,000 (15,000) [8000]-kw plant is $53 (62) [72].

MATHEMATICAL SIGNS AND SYMBOLS

$+$ plus (sign of addition)
$+$ positive
$-$ minus (sign of subtraction)
$-$ negative
$\pm$ ($\mp$) plus or minus (minus or plus)
$\times$ times, by (multiplication sign)
$\cdot$ multiplied by
$\div$ sign of division
$/$ divided by
$:$ ratio sign, divided by, is to
$::$ equals, as (proportion)
$<$ less than
$>$ greater than
$=$ equals
$\equiv$ identical with
$\approx$ approximately equals
$\leq$ equal to or less than
$\geq$ equal to or greater than
$\mp$ $\neq$ not equal to
$\doteq$ approaches
$\propto$ varies as
∞ infinity
$\sqrt{\ }$ square root of
$\sqrt[3]{\ }$ cube root of
$\therefore$ therefore
$\|$ parallel to
$(\,)\ [\,]\ \{\,\}$ parentheses, brackets and braces; quantities enclosed by them to be taken together in multiplying, dividing, etc.
$\overline{AB}$ length of line from A to B
π pi, $= 3.14159+$
μ microns $= 0.001$ mm
$\mu\mu$ micromillimeters $= 0.001\,\mu$
$^\circ$ degrees
$'$ minutes
$''$ seconds
$\angle$ angle
dx differential of x
Δ (delta) difference
Δx increment of x
$\partial u/\partial x$ partial derivative of u with respect to x
$\int$ integral of
$\int_a^b$ integral of, between limits a and b
Σ (sigma) summation of
$f(x)$, $F(x)$ functions of x
$4!$ factorial $4 = 1 \times 2 \times 3 \times 4$
$|x|$ absolute value of x

In the writing out of formulas the practice described in the first paragraph of p. 112 is followed throughout this book.

$\pi^2 = 9.86960 \quad (\pi/2)^2 = 2.46740 \quad 1/\pi^2 = 0.101321$

Explanation of Table of Squares (pp. 2–7).

This table gives the value of N^2 for values of N from 1 to 10, correct to four figures (Interpolated values may be in error by 1 in the fourth figure).

To find the square of a number N outside the range from 1 to 10, note that moving the decimal point one place in column N is equivalent to moving it two places *in the body of the table. For example:*

$(3.217)^2 = 10.35; \quad (0.03217)^2 = 0.001035; \quad (3217)^2 = 10350000$

This table can also be used inversely, to give square roots.

Explanation of Table of Cubes (pp. 8–11).

This table gives the value of N^3 for values of N from 1 to 10, correct to four figures. (Interpolated values may be in error by 1 in the fourth figure.)

To find the cube of a number N outside the range from 1 to 10, note that moving the decimal point one place in column N is equivalent to moving it three places in the body of the table. For example:

$(4.852)^3 = 114.2$; $(0.4852)^3 = 0.1142$; $(485.2)^3 = 114200000$

This table may also be used inversely, **to give cube roots.**

10.0	1000.0										

$\pi^3 = 31.0063$ $\qquad 1/\pi^3 = 0.0322515+$

Moving the decimal point ONE place in *N* requires moving it THREE places in body of table (see p. 10).

$\sqrt{\pi} = 1.77245+$ $\quad 1/\sqrt{\pi} = 0.56419 \quad \sqrt{\pi/2} = 1.25331 \quad \sqrt{e} = 1.64872$

Explanation of Table of Square Roots (pp. 12–15).

This table gives the values of $\sqrt{N}$ for values of N from 1 to 100, correct to four figures. (Interpolated values may be in error by 1 in the fourth figure.)

To find the square root of a number N outside the range from 1 to 100, divide the digits of the number into blocks of two (beginning with the decimal point), and note that moving the decimal point two places in N is equivalent to *moving it one place* in the square root of N. For example:

$$\sqrt{2.718} = 1.648; \quad \sqrt{271.8} = 16.48; \quad \sqrt{0.0002718} = 0.01648;$$

$$\sqrt{27.18} = 5.213; \quad \sqrt{2718} = 52.13; \quad \sqrt{0.002718} = 0.05213.$$

$\sqrt[3]{\pi} = 1.46459 \qquad 1/\sqrt[3]{\pi} = 0.682784$

Explanation of Table of Cube Roots (pp. 16–21).

This table gives the values of $\sqrt[3]{N}$ for all values of N from 1 to 1000, correct to four figures. (Interpolated values may be in error by 1 in the fourth figure.)

To find the cube root of a number N outside the range from 1 to 1000, divide the digits of the number into blocks of three (beginning with the decimal point), and note that moving the decimal point three places in column N is equivalent to moving it one place in the cube root of N. For example:

$$\sqrt[3]{2.718} = 1.396; \quad \sqrt[3]{2718} = 13.96; \quad \sqrt[3]{0.000002718} = 0.01396.$$
$$\sqrt[3]{27.18} = 3.007; \quad \sqrt[3]{27180} = 30.07; \quad \sqrt[3]{0.00002718} = 0.03007.$$
$$\sqrt[3]{271.8} = 6.477; \quad \sqrt[3]{271800} = 64.77; \quad \sqrt[3]{0.0002718} = 0.06477.$$

This table gives $N^{3/2}$ from $N = 1$ to $N = 100$. Moving the decimal point TWO places in N requires moving it THREE places in body of table. Thus:

$(7.23)^{3/2} = 19.44$; $(723.)^{3/2} = 19440$; $(0.0723)^{3/2} = 0.01944$

$(72.3)^{3/2} = 614.8$; $(7230.)^{3/2} = 614800$; $(0.723)^{3/2} = 0.6148$

Used inversely, table gives $M^{2/3}$ from $M = 1$ to $M = 1000$. Thus: $(0.6148)^{2/3} = 0.7230$.

THREE-HALVES POWERS (*continued*) (See also p. 20)

$1/\pi = 0.318310 \qquad 1/e = 0.367879$

Explanation of Table of Reciprocals (pp. 24–27).

This table gives the values of $1/N$ for values of N from 1 to 10, correct to four figures. (Interpolated values may be in error by 1 in the fourth figure.)

To find the reciprocal of a number N outside the range from 1 to 10, note that moving the decimal point any number of places in either direction in column N is equivalent to moving it the same number of places in the opposite direction in the body of the table. For example:

$$\frac{1}{3.217} = 0.3109; \quad \frac{1}{3217.} = 0.000\,3109; \quad \frac{1}{0.003217} = 310.9$$

Explanation of Table of Circumferences (pp. 28–29)

This table gives the product of π times any number D from 1 to 10; that is, it is a table of multiples of π. (D = diameter.)

Moving the decimal point **one** place in column D is equivalent to moving it **one** place in the body of the table.

$$\text{Circumference} = \pi \times \text{diam.} = 3.141593 \times \text{diam.}$$

Conversely,

$$\textit{Diameter} = \frac{1}{\pi} \times \textit{circumf.} = 0.31831 \times \textit{circumf.}$$

CIRCUMFERENCES BY HUNDREDTHS (*continued*)

Explanation of Table of Areas of Circles (pp. 30–31)

Moving the decimal point one place in column D is equivalent to moving it two places in the body of the table. (D = diameter.)

$$\text{Area of circle} = \frac{\pi}{4} \times (\text{diam.}^2) = 0.785398 \times (\text{diam.}^2)$$

Conversely,

$$\text{Diam.} = \sqrt{\frac{4}{\pi}} \times \sqrt{\text{area}} = 1.128379 \times \sqrt{\text{area}}$$

If given diameter is not found in this table, reduce diameter to feet and decimals of a foot by aid of the following auxiliary table, and then find area from pp. 30–31.

From Inches and Fractions of an Inch to Decimals of a Foot

Inches	1	2	3	4	5	6	7	8	9	10	11
Feet	.0833	.1667	.2500	.3333	.4167	.5000	.5833	.6667	.7500	.8333	.9167
Inches	1/8	1/4	3/8	1/2	5/8	3/4	7/8				
Feet	.0104	.0208	.0313	.0417	.0521	.0625	.0729				

Example. 5 ft 7 3/8 in. = 5.0 + 0.5833 + 0.0313 = 5.6146 ft

SEGMENTS OF CIRCLES, GIVEN h/c

Given: h = height; c = chord. (For explanation of this table, see p. 38)

$\frac{h}{c}$	$\frac{\text{Diam.}}{c}$	Diff.	$\frac{\text{Arc}}{c}$	Diff.	$\frac{\text{Area}}{h \times c}$	Diff.	Central angle, v	Diff.	$\frac{h}{\text{Diam.}}$	Diff.

Explanation of Table of Volumes of Spheres (pp. 36–37)

Moving the decimal point one place in column D is equivalent to moving it three places in the body of the table. (D = diameter.)

$$\text{Volume of sphere} = \frac{\pi}{6} \times (\text{diam.}^3) = 0.523599 \times (\text{diam.}^3)$$

Conversely,

$$\text{Diam.} = \sqrt[3]{\frac{6}{\pi}} \times \sqrt[3]{\text{volume}} = 1.240701 \times \sqrt[3]{\text{volume}}$$

NOTE. Vol. segm. = $\frac{1}{6}\pi h^2 (3D-2h)$.

Explanation of Table on this page

Given, h = height of segment,
D = diam. of sphere.

To find the volume of the segment, form the ratio h/D and find from the table the value of (vol./D^3); then, by a simple multiplication,

vol. segment = $D^3 \times$ (vol./D^3).

The table gives also the ratio of the volume of the segment to the entire volume of the sphere.

NOTE. Area of zone = $\pi \times h \times D$. (Use Table of Multiples of π, p. 28)

Explanation of Table on p. 34

Given, h = height of segment,
c = chord.

To find the diam. of the circle, the length of arc, or the area of the segment, form the ratio h/c, and find from the table the value of (diam./c), (arc/c), or (area/hc); then, by a simple multiplication,

diam. = $c \times$ (diam./c),
arc = $c \times$ (arc/c),
area = $h \times c \times$ (area/hc).

The table gives also the angle subtended at the center, and the ratio of h to D. See p. 106.

Explanation of Table on p. 35

Given, h = height of segment,
D = diam. of circle.

To find the chord, the length of arc, or the area of the segment, form the ratio h/D, and find from the table the value of (chord/D), (arc/D), or (area/D^2); then, by a simple multiplication,

chord = $D \times$ (chord/D),
arc = $D \times$ (arc/D),
area = $D^2 \times$ (area/D^2).

The table gives also the angle subtended at the center, the ratio of the arc of the segment to the whole circumference, and the ratio of the area of the segment to the area of the whole circle. See p. 106.

REGULAR POLYGONS

n = number of sides;
v = $360°/n$ = angle subtended at the center by one side;
a = length of one side $= R\left(2 \sin \frac{v}{2}\right) = r\left(2 \tan \frac{v}{2}\right)$;
R = radius of circumscribed circle $= a\left(\frac{1}{2} \csc \frac{v}{2}\right) = r\left(\sec \frac{v}{2}\right)$;
r = radius of inscribed circle $= R\left(\cos \frac{v}{2}\right) = a\left(\frac{1}{2} \cot \frac{v}{2}\right)$;
Area $= a^2\left(\frac{1}{4} n \cot \frac{v}{2}\right) = R^2\left(\frac{1}{2} n \sin v\right) = r^2\left(n \tan \frac{v}{2}\right)$.

BINOMIAL COEFFICIENTS

(For table giving binomial coefficients for fractional values of n, see p. 110).

$(n)_0 = 1$; $(n)_1 = n$; $(n)_2 = \frac{n(n-1)}{1 \times 2}$; $(n)_3 = \frac{n(n-1)(n-2)}{1 \times 2 \times 3}$; etc.; in general,

$(n)_r = \frac{n(n-1)(n-2)\ .\ .\ .\ (n-[r-1])}{1 \times 2 \times 3\ .\ .\ .\ \times r}$. Another notation: $\binom{n}{r} = (n)_r$.

1.49	1732	1735	1738	1741	1744	1746	1749	1752	1755	1758	

Moving the decimal point n places to the right [or left] in the number requires adding $+n$ [or $-n$] in the body of the table (see p. 42).

$\log \pi = 0.4971$ $\log \pi/2 = 0.1961$ $\log \pi^2 = 0.9943$ $\log \sqrt{\pi} = 0.2486$
$\log e = 0.4343$ $\log (0.4343) = 0.6378 - 1$

These two pages give the common logarithms of numbers between 1 and 10, correct to four places. Moving the decimal point n places to the right [or left] in the number is equivalent to adding n [or $-n$] to the logarithm. Thus, $\log 0.017453 = 0.2419 - 2$, which may also be written $\bar{2}.2419$ or $8.2419 - 10$. See p. 91. Graphs, p. 174.

$$\log (ab) = \log a + \log b \qquad \log (a^N) = N \log a$$

$$\log \left(\frac{a}{b}\right) = \log a - \log b \qquad \log \left(\sqrt[N]{a}\right) = \frac{1}{N} \log a$$

* NOTE: Do not interpolate in this column.

$e = 2.71828$; $1/e = 0.367879$ $\log_{10}e = 0.4343$ $1/(0.4343) = 2.3026$

$\log_{10}(0.4343) = \bar{1}.6378$ $\log_{10}(e^n) = n(0.4343)$

For table of multiples of 0.4343, see p. 62. Graphs, p. 174.

HYPERBOLIC LOGARITHMS

These two pages give the natural (hyperbolic, or Napierian) logarithms ($\log_e$) of numbers between 1 and 10, correct to four places. Moving the decimal point n places to the right [or left] in the number is equivalent to adding n times 2.3026 [or n times $\bar{3}.6974$] to the logarithm. Base $e = 2.71828+$

n	n (2.3026)	n (0.6974–3)
1	2.3026	0.6974-3
2	4.6052	0.3948-5

10.0	2.3026										

Moving the decimal point **n places to the right [or left]** in the number requires adding *n* times 2.3026 [or *n* times **(0.6974–3)] in the body of the table.** See auxiliary table of multiples on top of the preceding page.

If $x > 5$, $\sinh x = \frac{1}{2}(\epsilon^x)$ and $\log_{10} \sinh x = (0.4343)x + 0.6990 - 1$, correct to four significant figures. For table of multiples of 0.4343, see p. 62. Graphs, p. 174.

COMPOUND INTEREST. AMOUNT OF A GIVEN PRINCIPAL

The amount A at the end of n years of a given principal P placed at compound interest to-day is $A = P \times x$ or $A = P \times y$ or $A = P \times z$, according as the interest (at the rate of r per cent. per annum) is compounded annually, semi-annually, or quarterly; the factor x or y or z being taken from the following tables.

Values of x. (Interest compounded annually; $A = P \times x$.)

Years	$r = 2$	2½	3	3½	4	4½	5	6	7

Formula: $z = [1 + (r/400)]^{4n}$.

AMOUNT OF AN ANNUITY

The amount S accumulated at the end of n years by a given annual payment Y set aside at the end of each year is $S = Y \times v$, where the factor v is to be taken from the following table. (Interest at r per cent. per annum, compounded annually.)

Values of v

Years	$r = 2$	2½	3	3½	4	4½	5	6	7
1	1.0000	1.0000	1.0000	1.0000	1.0000	1.0000	1.0000	1.0000	1.0000

Formula: $v = \{[1 + (r/100)]^n - 1\} \div (r/100) = (z - 1) \div (r/100)$.

PRINCIPAL WHICH WILL AMOUNT TO A GIVEN SUM

The principal P, which, if placed at compound interest to-day, will amount to a given sum A at the end of n years is $P = A \times x'$ or $P = A \times y'$ or $P = A \times z'$, according as the interest (*at the rate of r per cent. per annum*) is compounded annually, semi-annually, or quarterly; the factor x' or y' or z' being taken from the following tables.

Values of x'. (Interest compounded annually; $P = A \times x'$)

Formula: $z' = [1 + (r/400)]^{-4n} = 1/z$.

ANNUITY WHICH WILL AMOUNT TO A GIVEN SUM (SINKING FUND)

The annual payment, Y, which, if set aside at the end of each year, will amount with accumulated interest to a given sum S at the end of n years is $Y = S \times v'$, where the factor v' is given below. (Interest at r per cent. per annum, compounded annually.)

Formula: $w = [1 - [1 + (r/100)]^{-n}] \div [r/100] = a/x.$

ANNUITY PROVIDED FOR BY A GIVEN CAPITAL

The annual payment Y provided for for a term of n years by a given capital C placed at interest to-day is $Y = C \times w'$. (Interest at r per cent. per annum, compounded annually; the fund supposed to be exhausted at the end of the term.)

WEIGHTS AND MEASURES

REVISED BY

H. W. BEARCE

(Originally prepared by Louis A. Fischer)

In the United States the measures of weight and length commonly employed are identical for practical purposes with the corresponding English units, but the capacity measures differ from those now in use in the British Empire, the U. S. gallon being defined as 231 cu in. and the bushel as 2150.42 cu in., whereas the corresponding British Imperial units are, respectively, 277.418 cu in., and 2219.344 cu in. (1 Imp gal = 1.2 U. S. gal, approx; 1 Imp bu = 1.03 U. S. bu, approx).

The metric system of weights and measures was legalized and its use made permissive in the United States by an Act of Congress, passed in 1866. In 1872, by the concurrent action of the principal governments of the world, it was agreed to establish an International Bureau of Weights and Measures near Paris. The convention was held, and the treaty signed in 1875. It was ratified by the United States in 1878.

Prior to 1893, the British Imperial yard was regarded as the real standard of the United States. In 1893, the Office of Weights and Measures (now Bureau of Standards) by executive order fixed the value of the United States yard in terms of the international meter, according to the ratio: one yard = 3600/3937 meters. At the same time, the pound was fixed in terms of the international kilogram, according to the relation: one pound = 453.5924277 grams.

U. S. Customary Weights and Measures

Measures of Length

12 inches	= 1 foot
3 feet	= 1 yard
5½ yards = 16½ feet	= 1 rod, pole, or perch
40 poles = 220 yards	= 1 furlong
8 furlongs = 1,760 yards = 5,280 feet	= 1 mile
3 miles	= 1 league
4 inches	= 1 hand
9 inches	= 1 span

Nautical Units

6,080.20 feet	= 1 nautical mile
6 feet	= 1 fathom
120 fathoms	= 1 cable length
1 nautical mile per hr	= 1 knot

Surveyor's or Gunter's Measure

7.92 inches	= 1 link
100 links = 66 ft = 4 rods	= 1 chain
80 chains	= 1 mile
33⅓ inches	= 1 vara (Texas)

Measures of Area

144 square inches	= 1 square foot
9 square feet	= 1 square yard
30¼ square yards	= 1 square rod, pole, or perch
160 square rods = 10 square chains = 43,560 sq ft = 5,645 sq varas (Texas)	= 1 acre
640 acres = 1 square mile	= 1 "section" of U. S. Govt. surveyed land
1 circular inch = area of circle 1 inch in diameter	= 0.7854 sq in.
1 square inch	= 1.2732 cir in.
1 circular mil	= area of circle 0.001 in. in diam
1,000,000 cir mils	= 1 cir in.

Measures of Volume

1,728 cubic inches	= 1 cubic foot
27 cubic feet	= 1 cubic yard
1 cord of wood	= 128 cu ft
1 perch of masonry	= 16½ to 25 cu ft

U. S. Customary Weights and Measures—(*continued*)

Measures of Volume

Liquid or Fluid Measure

4 gills	= 1 pint
2 pints	= 1 quart
4 quarts	= 1 gallon
7.4805 gallons	= 1 cubic foot

(There is no standard liquid barrel; by trade custom, 1 bbl of petroleum oil, unrefined = 42 gal)

Apothecaries' Liquid Measure

60 minims = 1 liquid dram or drachm
8 drams = 1 liquid ounce
16 ounces = 1 pint

Water Measure

The **miner's inch** is the quantity of water that will pass through an orifice 1 sq in. in cross section under a head of 4 to 6½ in., as fixed by statutes, and varies from 1/40 cu ft to 1/50 cu ft per sec. The units now most in use are 1 cu ft per sec and 1 gal per sec, the U. S. Reclamation Service employing the former. See p. 257.

Dry Measure

2 pints = 1 quart
8 quarts = 1 peck
4 pecks = 1 bushel

1 std bbl for fruits and vegetables = 7056 cu. in. or 105 dry qt, struck measure

Shipping Measure

1 Register ton = 100 cu ft
1 U. S. shipping ton = 40 cu ft = 32.14 U. S. bu *or* 31.14 Imp bu
1 British shipping ton = 42 cu ft = 32.70 Imp bu or 33.75 U. S. bu

Board Measure

1 board foot = 144 cu in. = volume of board 1 ft sq and 1 in. thick.

The international log rule, based upon ¼ in. kerf, is expressed by the formula

$$X = 0.904762\,(0.22D^2 - 0.71D)$$

where X is the number of board feet in a 4 ft section of a log and D is the top diam in in. In computing the number of board feet in a log the taper is taken at ½ in. per 4 ft linear, and separate computation is made for each 4 ft section.

Weights
(The grain is the same in all systems)

Avoirdupois Weight

16 drams = 437.5 grains	= 1 ounce
16 ounces = 7,000 grains	= 1 pound
100 pounds	= 1 cental
2,000 pounds	= 1 short ton
2,240 pounds	= 1 long ton
1 std lime bbl, small	= 180 lb net
1 std lime bbl, large	= 280 lb net

Also (in Great Britain):

14 pounds	= 1 stone
2 stone = 28 lb	= 1 quarter
4 quarters = 112 lb	= 1 hundredweight (cwt)
20 hundredweight	= 1 long ton

Troy Weight

24 grains	= 1 pennyweight (dwt)
20 pennyweights = 480 grains	= 1 ounce
12 ounces = 5,760 grains	= 1 pound

1 Assay Ton = 29,167 milligrams, or as many milligrams as there are troy ounces in a ton of 2,000 lb avoirdupois. Consequently, the number of milligrams of precious metal yielded by an assay ton of ore gives directly the number of troy ounces that would be obtained from a ton of 2,000 lb avoirdupois.

Apothecaries' Weight

20 grains	= 1 scruple ℈
3 scruples = 60 grains	= 1 dram ʒ
8 drams	= 1 ounce ℥
12 ounces = 5,760 grains	= 1 pound

Weight for Precious Stones

1 carat = 200 milligrams
(Used by almost all important nations.)

Circular Measure

60 seconds	= 1 minute
60 minutes	= 1 degree
90 degrees	= 1 quadrant
360 degrees	= circumference
57.2957795 degrees (= 57° 17′44.806″)	= 1 radian (or angle having arc of length equal to radius)

METRIC SYSTEM

The fundamental units of the metric system are the meter (the unit of length) and the kilogram (the unit of mass). The unit of volume, the cubic decimeter (which was also designated the liter), and the unit of mass, the kilogram, were originally derived from the meter. The kilogram and the meter are now defined independently, and the liter is defined as the volume of a kilogram of water at the temperature of its maximum density, 4 C,

and under a pressure of 76 cm of mercury. The liter is slightly greater than the cubic decimeter, and according to the best information, 1 liter = 1.000027 cubic decimeters.

The U. S. customary lengths, areas, and cubic measures derived from the international meter are based on the relation 1 meter equals 39.37 inches (exactly), or 1 yard equals 0.9144018 meter.

The U. S. customary weights derived from the international kilogram are based on the value 1 avoirdupois lb = 453.5924277 grams. The value of the troy lb is based on the same relation and also the equivalent 5,760/7,000 avoirdupois lb equals 1 troy lb.

Metric Measures

Length			Area		
Unit	Symbol	Value in meters	Unit	Symbol	Value in sq. meters
Micron	μ	0.000001	...	...	...

Gram (unit)	g	1.0	Quintal	q	100,000.0
...	...	...	Ton	t	1,000,000.0

The unit of **force** defined dynamically is the dyne (p. 73); the megadyne is one million dynes. The unit of force defined by gravity is the kilogram force = 980×10^3 dynes approximately. A subsidiary unit is the milligram (gram) [ton] force which is equal to 10^{-6} (10^{-3}) [10^3] kilogram force.

SYSTEMS OF UNITS

The principal units of interest to mechanical engineers can all be derived from the three fundamental units of **force, length,** and **time.** These three fundamental units may be chosen at pleasure; each such choice gives rise to a "system" of units. The following table gives the units of the four "systems" most often met with in the literature.

The precise definitions of the units of force in these systems are as follows. In these definitions the "standard pound body" and the "standard kilogram body" refer to two material standards of mass, carefully preserved at London and Paris, respectively (the U. S. pound is derived from the kilogram); the "standard locality" means sea level, 45 deg latitude, or, more strictly, any locality in which the acceleration due to gravity has the value 980.665 cm per sec² = 32.1740 ft per sec², which may be called the standard acceleration.

The pound force is the force required to support the standard pound body against gravity, *in vacuo*, in the standard locality; or, it is the force which, if applied to the standard pound body, supposed free to move, would give that body the "standard acceleration." The word "pound" is used for the unit of both force and mass and consequently is ambiguous. To avoid uncertainty it is desirable to call the units "pound force" and "pound mass," respectively.

The kilogram force is the force required to support the standard kilogram against gravity, *in vacuo*, in the standard locality; or, it is the force which, if applied to the standard kilogram body, supposed free to move, would give that body the "standard acceleration." The word "kilogram" is used for the unit of both force and mass and consequently is ambiguous. To avoid uncertainty it is desirable to call the units "kilogram force" and "kilogram mass," respectively.

The poundal is the force which, if applied to the standard pound body, would give that body an acceleration of 1 ft per sec²; that is, 1 poundal = 1/32.1740 lb force.

The dyne is the force which, if applied to the standard gram body, would give that body an acceleration of 1 cm per sec²; that is, 1 dyne = 1/980.665 of a gram force.

Systems of Units

Name of unit	Dimensions of units in terms of F, L, T	British "gravitational" system, or "foot-pound-second" system	Metric "gravitational" system, or "kilogram-meter-second" system	Metric "absolute" system, or "C. G. S." system	British "absolute" system (little used)
Force	F	1 lb	1 kg	1 dyne	1 poundal
Length	L	1 ft	1 m	1 cm	1 ft
Time	T	1 sec	1 sec	1 sec	1 sec
Velocity	L/T	1 ft per sec	1 m per sec	1 cm per sec	1 ft per sec
Acceleration	L/T^2	1 ft per sec²	1 m per sec²	1 cm per sec²	1 ft per sec²
Pressure	F/L^2	1 lb per ft²	1 kg per m²	1 dyne per cm²	1 pdl per ft²
Impulse or momentum	FT	1 lb-sec	1 kg-sec	1 dyne-sec	1 pdl-sec
Work or energy	FL	1 ft-lb	1 kg-m	1 dyne-cm = 1 "erg"	1 ft-pdl
Power	FL/T	1 ft-lb per sec	1 kg-m per sec	1 dyne-cm per sec	1 ft-pdl per sec
Mass	$F/(L/T^2)$	1 lb per (ft per sec²) = 1 "slug."	1 kg per (m per sec²) = 1 "metric" slug."	1 dyne per (cm per sec²) = 1 gram mass.	1 pdl per (ft per sec²) = 1 pound mass.

NOTE. The "slug" (also called the "geepound," or the "engineer's unit of mass"), the "metric slug," and the "poundal" are never used in practice.

Other common units are as follows:

Work: 1 joule (absolute) = 10^7 ergs = 10,000,000 dyne-cm
1 kilowatt-hour (international) = 3,600,000 joules (international) = 3,600.864 $\times 10^{10}$ dyne-cm = 3,600,864 joules (absolute)

Power: 1 horsepower = 550 ft-lb per sec
1 poncelet = 100 kg-m per sec
1 cheval-vapeur = 75 kg-m per sec = 1 metric horsepower = 1 Pferde Starke
1 watt (international) = 1 joule (international) per sec = 1.00024 $\times 10^7$ dyne-cm per sec = 1.00024 joules (absolute) per sec
1 kilowatt = 1,000 watts = 10^{10} dyne-cm per sec

A new horsepower of 550.220 ft-lb per sec, or 746 watts, has been proposed, but has not been accepted by mechanical engineers.

The *weight* of a body (in a given locality) means a *force*, namely, the force, required to support the body against gravity (in that locality). When no particular locality

is specified, the standard locality may be assumed. Thus, the "standard weight" of the pound body is 1 lb force; the "standard weight" of the kilogram body is 1 kg force.

Heat Units. The units of heat commonly used are (1) the quantity of heat required to raise the temperature of 1 gram of water 1 C and (2) the quantity of heat required to raise the temperature of 1 pound of water 1 F. These units are (1) the **calorie** and (2) the **British thermal unit** or Btu. Work done in recent years on the International Steam Tables has led to the definition of the **IT calorie** and of the Btu in terms of other units. These definitions are

$$1 \text{ IT calorie} = \tfrac{1}{860} \text{ international watt-hour}$$
$$1 \text{ Btu} = 251.996 \text{ IT calories}$$

These units have been used on the following pages. The **kilocalorie**, some-

* Example: 1 in. = 25.40 mm.

times called the kilogram calorie or large calorie, is equal to 1,000 calories and is used in engineering work in metric countries. The calorie is sometimes called the small calorie or gram calorie.

The mean calorie (0 to 100 C) is about 1.001 IT calorie, and the corresponding mean Btu is approximately 779 ft-lb.

Mechanical Equivalent of Heat. The values now accepted as the work equivalents of the heat units are 778.2 ft-lb for the Btu and 4.187 absolute joules for the IT calorie.

The equivalents are given in the heavier type. Logarithms of the equivalents are given immediately below. In some cases the equivalents have been rounded off, while the logarithm corresponds to the equivalent carried to a greater number of decimal places.

Subscripts after any figure, 0_3, 9_4, etc., mean that that figure is to be repeated the indicated number of times.

Conversion of Areas*

BOILERS AND FUELS

BY

DAVID M. SCHOENFELD and GEORGE P. HAYNES

STEAM PRESSURES AND TEMPERATURES

For merchant vessels using geared turbines or turboelectric propulsion the most popular design conditions for the steam-generating units seem to be 450 psi gage and 750 F; but, with tendencies toward higher pressures and temperatures, an increasing number of vessels are being built or are in operation using 600 psi gage and 850 F steam conditions. This is also the standard for combat vessels of the Navy.

One merchant ship has been built under U.S. Maritime Commission sponsorship utilizing 1,200 psi gage and 750 F with provision for reheating the steam.* A number of other vessels, in which the boilers will generate steam at 1,450 psi gage and 750 F with reheating provisions, are under construction for private interests.

The gains that may be achieved with pressures up to 1,450 psi gage and temperatures up to 950 F figure as follows:

Pressure, psi gage	Temperature, deg F	Approximate fuel reduction, %
450	750	0
600	850	6
900	900	10
1,450	950	13
1,450	750 (1 steam reheat)	9
	(2 steam reheat)	11
1,450	750 (1 gas reheat)	11

High-pressure boilers are smaller for a given shaft horsepower, and the initial cost is only slightly greater than for lower pressures. They introduce no particular problem in boiler design, although care should be taken to assure ample circulation in the boiler and waterwalls where headroom is restricted. High steam temperature requires special consideration of such matters as the location and size of the superheater, the design of the furnace so as to produce the required gas temperatures at the superheater, and the selection of materials for and the design of the superheater elements and the steam piping and valves. Moreover, in order to protect the turbine from excessive temperature, it is necessary to employ closer control of the superheat where high steam temperatures are involved.

Where engines are used instead of turbines for propulsion, as in the case of the vast number of Liberty ships constructed during the war, lower steam pressures and temperatures are usually selected. Pressures generally are not in excess of 300 psi gage; usually in the range of 200 to 275 psi gage. Tem-

erally by magnetic examination of other welds; then by annealing the entire drum to relieve the stresses built up during welding.

Forced-circulation boilers depend upon mechanical means (pumps) to provide or assist circulation, rather than differences in density of water and steam, produced thermally. Wide flexibility of design results, permitting disposition of heating surfaces for most effective heat absorption, compactness of arrangement, and a saving of steel and weight especially in boilers designed to operate at high pressures of 1,200 psi and above. They have had wider

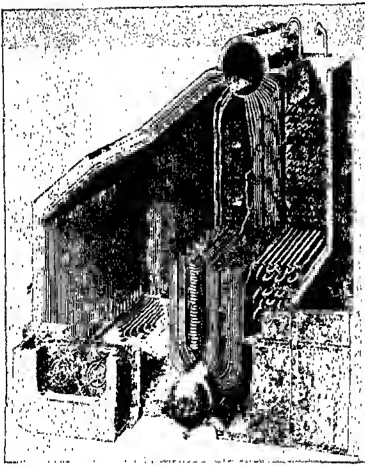

FIG. 10.—Foster Wheeler D type two-drum bent-tube boiler with vertical tube bank.

application in foreign ships than in this country. Here the applications have been mostly of an experimental nature in naval vessels. Nevertheless, with a definite trend toward higher steam pressures and temperatures, forced-circulation boilers particularly in the larger sizes required for highly powered ships are sure to receive increasing attention.

Some forced-circulation boilers are of the "once-through" type such as the Benson, Sulzer, and Besler. Such boilers have no drums. The water is forced by a high-pressure feed pump into one or more tubes (also known as circuits) and steam is delivered at the outlets. Steam demand requires such sensitive response of the fuel supply and feed pump that automatic controls are invariably used. Any impurities in the feed water are either deposited

peratures as high as 640 F have been employed but more commonly they are in the range of 450 to 550 F.

For steam conditions of 450 psi gage and 750 F and higher pressures and temperatures, it is usual to design the steam-generating units for 87 to 88 percent efficiency. To reach such efficiencies requires the use of economizers or air heaters, or a combination of the two, to reduce the temperature of the flue gases leaving the boiler. The choice between economizers or air heaters, or a combination, is generally dictated by the number of stages of feed heating selected, and this selection in turn is affected by economic and operating considerations.

For two stages of feed heating, the temperature of the boiler feed is usually about 240 F, for three stages about 315 to 320 F, and for higher pressures, as high as 385 to 420 F, depending on the number of stages and pressures selected for bleeding. With a feed-water temperature of 240 F, economizers may be used to reach 87 or 88 percent efficiency, but generally an air heater becomes too bulky to fit into the design. With a feedwater temperature of 315 to 320 F, an economizer becomes too bulky but an air heater may be used satisfactorily for these efficiencies. A combination of both economizer and air heater is used when the feed-water temperature is 385 to 420 F. These general statements of course are predicated on the provision of enough boiler surface to reduce the temperature of the flue gases to satisfactory design values. The proportions of heating surface to be incorporated in the furnace, boiler, superheater, economizer, and air heater will vary with the steam pressure and temperature, and with the ideas of different designers and operators.

The effect of economizer and air-heater surface is to increase the efficiency of the steam-generating unit by from 5 to 10 percent, the amount increasing with higher steam pressure.

BOILER TYPES

Scotch Boilers. In the earlier days of steam-propelled vessels, various kinds and designs of boilers were employed. However, owing to structural weakness, insufficient capacity, poor efficiency, or excessive weight, these unsuitable types were gradually discarded as requirements became more severe until, at present, with a few isolated exceptions, there are only two types in general use: the Scotch and the watertube, with the latter predominating. Figure 1 illustrates a Scotch marine boiler with an air preheater and fire-tube superheater.

The Scotch boiler came into use nearly a hundred years ago in Caledonian shipyards; hence the name. For many years it was the most favored type with the lower steam pressures then prevailing. It gave place to the water-tube type only when improved designs of greater capacity and efficiency, less weight, and the ability to operate at higher pressures were developed. However, under certain conditions and for certain purposes it still is regarded favorably. Its strong features are large steam space, ease of maintenance and repair, ability to use feed water of doubtful quality, and adaptability to practically any fuel. Its more undesirable limitations are excessive weight, sluggish circulation, limited pressure, relatively low capacity, and low efficiency. As usually constructed, such boilers for marine service vary from approximately 10 to 18 ft in diameter and from 10 ft 6 in. to 12 ft long. They are equipped with from two to four corrugated furnaces—the customary number being three—and with from one to four combustion chambers.

in the zone where transition from water to steam takes place or are carried over into the turbine and deposited on the blading. To avoid overheating of the zone where such deposits occur this section is usually located in a region of relatively low gas temperature and where no radiant heat will be received.

A variation of the foregoing is the type known as "spill-over," such as the "Steamotive." It is similar, but about 10 percent more water is forced through the circuits than will be transformed into steam. The mixture is discharged into a separating drum, whence the steam passes to the superheater

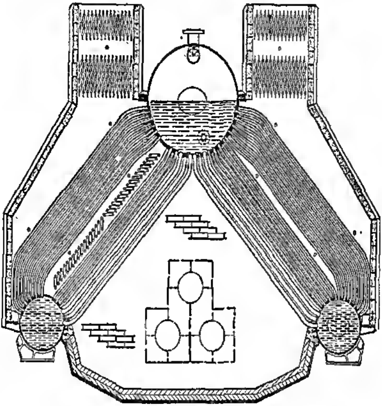

Fig. 11.—Combustion Engineering type V3M three-drum bent-tube boiler with superheater and economizers.

and the residual spill-over water is withdrawn through a pressure-reducing resistance and feed heater back to the feed-pump suction.

Other forced-circulation boilers are of the "assisted" circulation type in which a pump receives water from a drum and forces it through the tubes or circuits, the mixture of steam and water from the tubes being discharged back into the drum. Here separation occurs, the steam passing to the superheater, the water to the pump for recirculation. In the La Mont type, orifices are placed at the entrance to each tube circuit so that each circuit receives a quantity of water in proportion to the amount of steam generated in it. The amount of water circulated varies from three to eight times the quantity of steam generated. The circulating pump operates at a differential pressure head of 30 to 40 psi and requires power equivalent to 0.3 to 0.5 percent of the boiler output.

A group of tubes extends from each combustion chamber to the front head. The front head has openings to accommodate the furnaces, and holes for the tubes, access, and inspection. Flat surfaces are supported by through stays or by bridge or dog stays.

Furnaces are cylindrical shells with circumferential corrugations to afford strength against collapse and to provide for expansion. If oil fuel is used, burners are applied by means of a suitable furnace front behind which

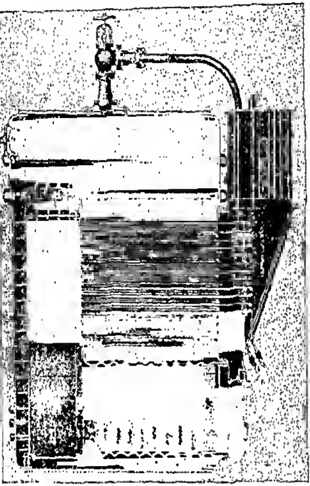

FIG. 1.—Scotch marine boiler with air heater and fire-tube superheater arranged for oil firing.

refractory is placed. With coal, grates are placed approximately on the horizontal center of the furnace. To direct air through the fuel bed a wall is erected at the rear of the grate. This wall closes the segmental area below the grate and also projects above the grate. Fronts include fire and ash doors, also connections to receive air from the forced-draft system and dampers to restrict flow when the fire door is open.

Customary practice is to provide each furnace with a separate combustion chamber. The purpose of the combustion chamber is to allow combustion to be completed and to distribute the flue gases to the tubes.

The Velox boiler is also of the assisted-circulation type but differs in that combustion is carried out under pressure usually varying from 20 to 35 psi. High combustion rates are attained, and high velocities of the gases over the heating surface permit high rates of heat absorption. The pressure of the gases leaving the heating surfaces operates a gas turbine driving a compressor

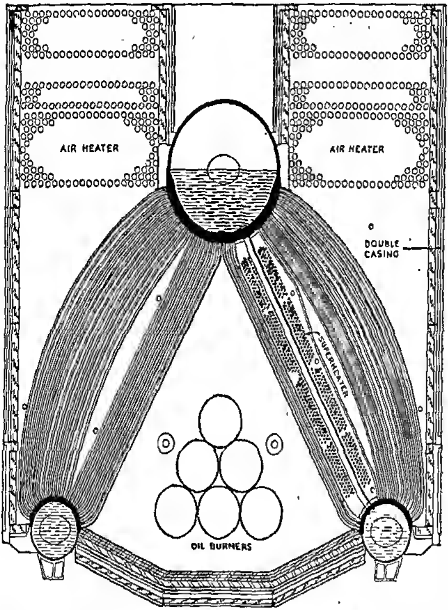

FIG. 12.—Babcock and Wilcox express type three-drum bent-tube boiler with superheater and air heaters.

which furnishes the air for combustion. The pressure at which steam is generated is optional.

In the Loeffler forced-circulation boiler, steam is generated by bubbling superheated steam through water in a drum located outside of the boiler setting. This steam is forced by a steam pump through tubes arranged both

The largest amount of heating surface is that in the tubes which are arranged in groups between the combustion chambers and the front head. Usually they are approximately 8 ft long and the customary sizes range from 2½ to 3½ in. in diameter. Tubes are of two kinds: plain and stay. Plain tubes have relatively thin walls and are held in position and made tight in their respective holes in the sheets by expanding or by rolling and beading.

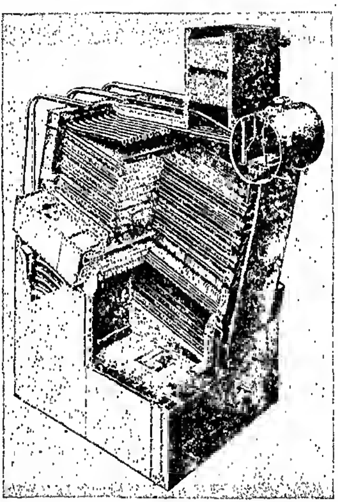

FIG. 2.—Combustion Engineering type SM sectional-header boiler as installed in Victory ships.

Stay tubes are thick walled, the ends of which usually are thickened to compensate for threading. Such tubes are used for staying tube sheets into which they are screwed and expanded. The customary ratio of plain to stay tubes is 4:1 or 5:1.

The Scotch boiler lends itself readily to the application of tubular air heaters in the uptake immediately above the boiler tubes.

Superheaters of the waste-gas or fire-tube type may be applied to new or existing boilers. Waste-heat superheaters consist of inlet and outlet headers connected by elements and are located in a horizontal position immediately

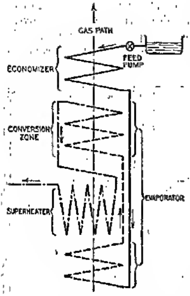

FIG. 13.—Schematic arrangement of once-through forced-circulation boiler, such as the Benson, Sulzer, and Besler types.

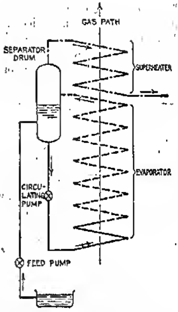

FIG. 14.—Schematic arrangement of controlled forced-circulation boiler with circulating pump—the La Mont type.

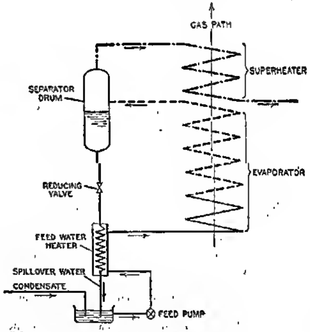

FIG. 15.—Schematic arrangement of spill-over type of forced-circulation boiler, such as the "Steamotive."

under the air heater where they are traversed by gases after they have left the boiler. Resulting superheat is of low degree. For higher superheat fire-tube superheaters are employed. These consist of one or more pairs of headers placed in the uptake and attached to the boiler head. They are connected by elements, each of which is arranged with several loops that extend into the boiler tubes.

Watertube Boilers. Current steam-generating practice in the United States employs almost exclusively watertube boilers. Fire-tube boilers or Scotch boilers are now rarely used. The watertube boilers are of two principal designs: (1) the straight-tube, header type, shown in Figs. 2 to 4, and

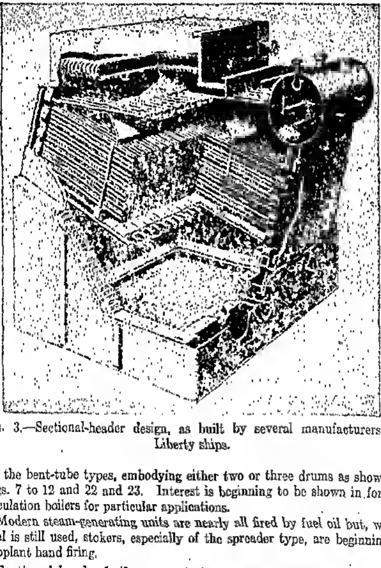

FIG. 3.—Sectional-header design, as built by several manufacturers for Liberty ships.

(2) the bent-tube types, embodying either two or three drums as shown in Figs. 7 to 12 and 22 and 23. Interest is beginning to be shown in forced-circulation boilers for particular applications.

Modern steam-generating units are nearly all fired by fuel oil but, where coal is still used, stokers, especially of the spreader type, are beginning to supplant hand firing.

Sectional-header boilers are suitable for steam pressures up to about 750 psi. They are available in sizes up to about 60,000 to 75,000 lb steam per hr. Tube sizes used vary from 4 to 1 in. O.D. When 4 and 2 in. O.D. tubes are used, the boiler is provided with baffles or flame plates to direct the flue gases in three passes over the bank of tubes. When 1¼ or 1 in. O.D.

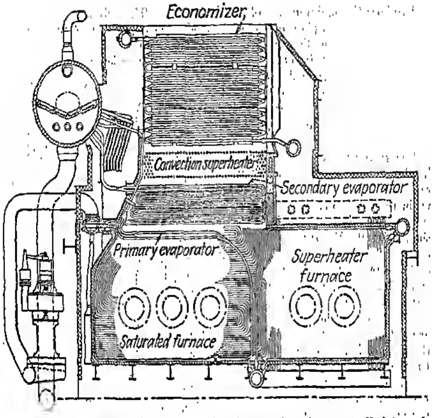

Fig. 16.—Cross section of recent Combustion Engineering controlled forced-circulation boiler, operating on principle shown in Fig. 14.

as wall cooling for the furnace and as a convection section where it is superheated. Superheating is completed in the convection section from which one portion goes to the prime mover, the remainder passing back to the drum where it generates saturated steam. Solids are precipitated in the drum out of the zones where heat absorption takes place. This type of boiler is seldom built for pressures less than 1,700 to 1,900 psi on account of the huge volumes of steam that the pump would have to handle at low pressures with consequent high power requirement. These several types of boilers are represented diagrammatically by Figs. 13 to 17.

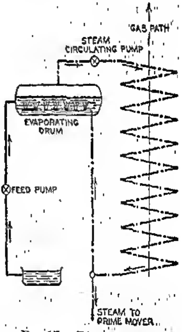

Fig. 17.—Diagram of forced-circulation boiler with circulating steam pump—Loeffler design.

FURNACES

Furnaces may be entirely of refractory construction, or water-cooled surface in the form of waterwalls may be applied to one or more walls. Even the floor of the furnace may be partly or completely water-cooled. Waterwalls permit high rates of heat release

tubes are used no baffles are employed and the gases make only a single pass over the tube bank.

The headers are generally rectangular in cross section and sinuous, so that lanes may be avoided through which the flue gases might by-pass or short-circuit the tubes, and the tubes are arranged in groups for accessibility for inspection, cleaning, or replacement through the handholes in the headers.

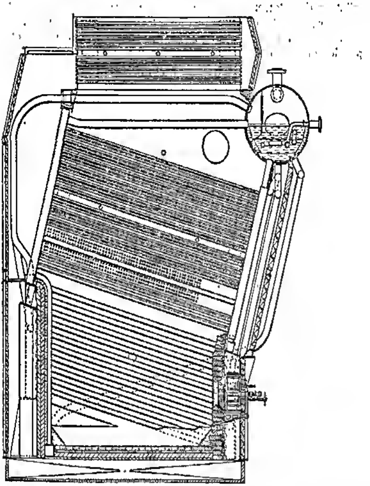

FIG. 4.—Babcock and Wilcox design of sectional-header marine boiler.

Hand holes are secured in place by arches, nuts, and washers and are sealed by gasketed seats. Details of a typical header with its handholes and parts are shown in Fig. 5.

Common practice provides under a single handhole, one 4 in. O.D. tube, or groups of either four 2 in. O.D. tubes, nine $1\frac{1}{4}$ in. O.D. tubes, or fourteen 1 in. O.D. tubes. Different combinations of these groupings may be used in the boiler as may be found desirable. Several widely used arrangements are illustrated in Fig. 6.

The location of the superheater is determined by the temperature of the flue gases required to secure the desired degree of superheat. A commonly used arrangement is indicated in Figs. 2 and 4. This is known as an "inter-

and reduce the maintenance of the brickwork. The tubes comprising the waterwalls may be plain or have extended surfaces. When plain tubes are used, they are generally arranged substantially tangent to each other. Such tubes are usually 2 in. O.D. When tubes with extended surface are used, they are usually spaced approximately two diameters from each other, and a portion is covered by a refractory material such as plastic chrome ore.

The furnace under a sectional-header boiler may be entirely of refractory construction, or waterwalls may be applied to the two side walls and the rear wall. On the side walls, the tubes are commonly disposed at the same slope as those in the boiler bank and are expanded into headers arranged vertically at the front and the rear of the boiler. The front headers are fed by downcomer tubes, and the rear headers are relieved by riser tubes connected to the steam and water drum. Vertical side waterwalls have been used. In the rear, vertical waterwall tubes are used, extending from a transverse header at the floor of the furnace upward to the uptake headers of the boiler. Downcomer tubes from the steam and water drum feed the lower header.

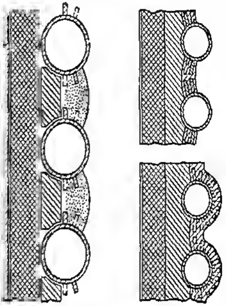

FIG. 18.—Typical details of waterwalls of sectional header boiler furnaces—left, Combustion Engineering; right, Babcock and Wilcox.

Furnaces of two-drum bent-tube boilers are always provided with water-cooled surface on the side walls and roof. The rear wall is often similarly water-cooled and occasionally even the front or burner wall. For the side

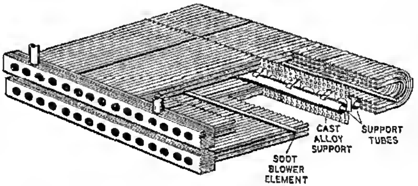

FIG. 19.—Hair-pin type of superheater as applied to a sectional-header boiler.

wall and roof a header is provided at the base of the side wall parallel to the water drum. This header is fed either by large diameter tubes, 4 or $4\frac{1}{2}$ in. O.D. extending from the steam and water drum downward to the outer ends of the header, or alternatively by a number of smaller tubes extending from

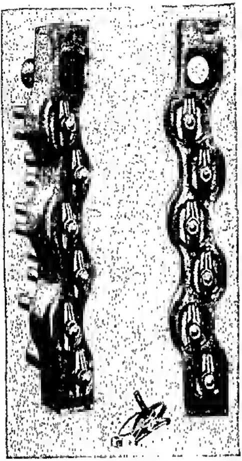

FIG. 5.—Typical header and handhole fittings.

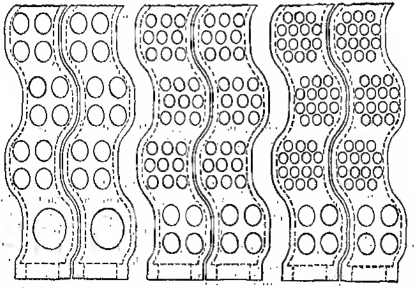

FIG. 6.—Variety of tube arrangements in headers.

the water drum across the floor of the furnace and enclosed in the refractory. The latter arrangement provides a partly water-cooled floor and assures good distribution of water all along the sidewall header. The tubes of the sidewall and roof discharge directly into the steam and water drum. When water cooling is applied to the rear or front wall, headers are provided at the floor and at the roof. The lower header is fed by a number of small tubes from the outer drum. Risers connect the upper header to the steam and water drums.

Various waterwall constructions are indicated in Figs. 2, 4, 7, 8, 10, and 12; details are shown in Fig. 18.

The rates of heat release in furnaces vary. In merchant practice the range is generally between 50,000 and 125,000 Btu/(cu ft)(hr) at normal power. The choice depends largely on the designer and the operator. Rates far in excess of these figures characterize practice in naval boilers.

SUPERHEATERS AND DESUPERHEATERS

Superheaters are either of the "hairpin" or the forged-return-bend types as illustrated in Figs. 19 and 20. The arrangement of the superheaters in the different types of boiler is evident from the typical examples shown, the design being dependent on the type of boiler, degree of superheat, fuel characteristics, type of service, etc. The desuperheater provides steam at lower temperature for auxiliaries.

For steam temperatures up to about 750 F, carbon-steel tubing has proved generally satisfactory for superheater tubes. For higher temperatures, of 800 to 850 F, carbon-molybdenum or low-chromium alloy steels are commonly used. For still higher temperatures alloy steels containing chromium and nickel are employed. The superheaters are usually designed so that only those portions subjected to these higher temperatures are constructed of these more expensive materials.

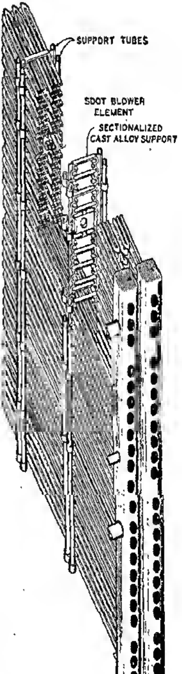

FIG. 20.—Forged return-bend superheater as applied to a two-drum bent-tube boiler.

Desuperheaters should always be fitted on boilers in which the superheaters are located in a zone where the temperature of the flue gases may be

deck" superheater. Space for a superheater is obtained by omitting from the tube bank a suitable number of tubes. Sometimes a different arrangement known as an "overdeck" or "doghouse" superheater is used as in Fig. 3.

Bent-tube boilers are generally of the two-drum design as in Figs. 7 to 10. The three-drum or so-called Yarrow type of boiler, shown in Figs. 11 and 12,

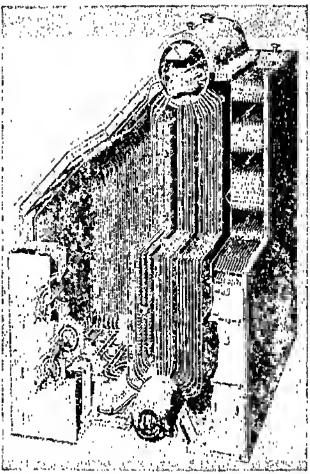

Fig. 7.—Combustion Engineering type V2M two-drum bent-tube boiler with vertical tube bank.

seems to have lost its former popularity, probably owing to its high cost and the complications involved in applying superheaters and economizers or air heaters, as well as in the uptakes. The tube banks of two-drum boilers may be arranged either vertically or inclined as shown by Figs. 7 to 10 which also indicate the customary arrangement of superheaters. Although two bent-tube boilers are sometimes arranged in a single boiler casing, the tendency in general favors each boiler in its individual casing. Both gastight single or double casings are available. Many all-welded casings have supplanted flanged casings previously used.

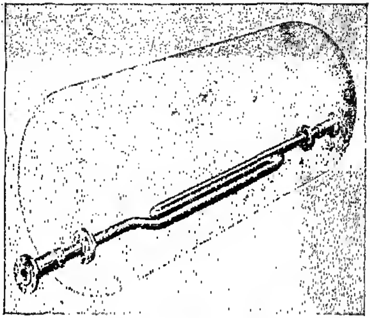

FIG. 21.—Desuperheater in boiler drum.

FIG. 22.—Foster Wheeler bent-tube boiler with separately fired superheater.

Tube sizes for these boilers are almost always 2 and $1\frac{1}{4}$ in. O.D. in merchant vessels, the former in the front bank, the latter in the rear bank. The corresponding naval practice uses $1\frac{1}{2}$ and 1 in. O.D.

The vertically arranged tube bank generally requires the use of baffles to direct the flue gases over the bank to secure proper heat absorption. Baffles are seldom required when the inclined tube bank is used.

Bent-tube boilers, especially the two-drum type, have achieved considerable popularity in recent years. Compared to sectional-header boilers, their weight and cost are relatively low. However, such boilers are inherently

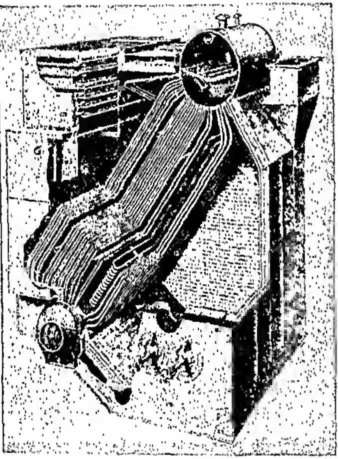

FIG. 8.—Combustion Engineering type V2M two-drum bent-tube boiler, with inclined tube bank.

susceptible to slower repair or cleaning since they must be cooled before the drum can be entered for access to the tubes. Cooling requires considerable time to prevent damage to the pressure parts and setting. On the other hand, access to the tubes of a sectional-header boiler can be had through the handholes in the headers in a much shorter time.

The design of bent-tube boilers, especially for high rates of evaporation per square foot of heating surface, requires the use of downcomer tubes located outside the path of the hot gases. These connect the steam and water drums and are usually located outside the boiler setting. The size of downcomers usually varies between $3\frac{1}{4}$ and $4\frac{1}{2}$ in. O.D. to reduce the number

expected to exceed 800 F. Otherwise, damage to superheaters is liable to occur under certain operating conditions, where the amount of steam required for auxiliaries is large and the amount of superheated steam is smaller by comparison. Under these circumstances, when the auxiliary steam is taken from the drum, not enough steam will pass through the superheater and it will overheat and deteriorate. Desuperheaters as commonly used are of the convection type located in the steam and water drum and arranged for with-

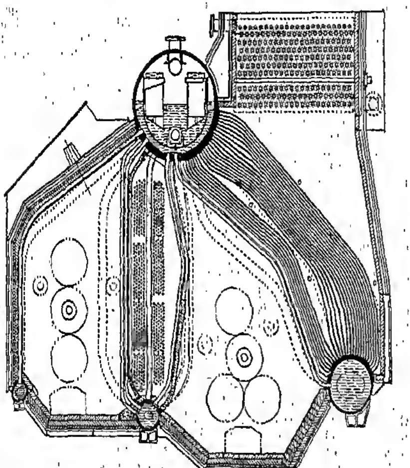

FIG. 23.—Babcock and Wilcox bent-tube boiler with separately fired superheater.

drawal through the manhole for repair or replacement (see Fig. 21). Desuperheaters are sometimes called **attemperators.**

Separately fired superheaters to provide constant superheat temperature over a wide range of steam output are available where the additional expense of such an arrangement may be justified. Such designs are shown in Figs. 22 and 23. The separately fired superheater is of the radiant type and is located in an auxiliary furnace adjacent to the main boiler furnace. The burners in the superheater furnace are fired at a rate suitable to maintain the desired total steam temperature. The flue gases pass from the superheater furnace into the main furnace through the common wall. The main furnace is fired at a rate suitable to maintain the required steam pressure and output.

required. The area in the downcomers is determined by several factors, principally the rate of heat input to the boiler and the distance between the steam and water drums.

Downcomer tubes are always used to supply the water to waterwalls. The *location of downcomer tubes with respect to swash plates in steam drums* should receive careful consideration.

Sectional-header boilers may be installed with the drums arranged either fore and aft in the vessel, or athwartship. The former is to be preferred

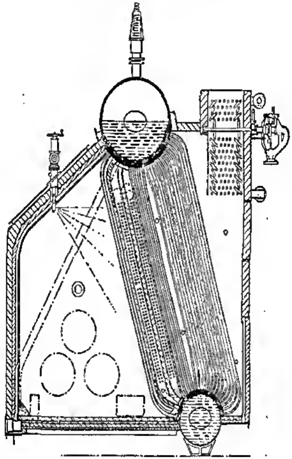

FIG. 9.—Babcock and Wilcox two-drum bent-tube boiler with inclined tube bank.

whenever possible since the motion of the ship in a seaway causes less disturbance of the water in the drums. Bent-tube boilers are always installed with the drums in a fore-and-aft direction.

Present practice no longer uses riveted drums, all drums now being manufactured by electric welding. This progressive step produces lighter, stronger drums with savings in time and expense. Furthermore, such drums are not subject to the phenomenon known as "caustic embrittlement" (arising out of improper workmanship and incorrect feed-water treatment). The welding operation is followed by an X-ray examination of all welded seams and gen-

Superheater supports are subjected to higher temperatures than the superheater tubes. To provide long life and to resist oxidation and deformation, it is customary to make them of high-chromium and nickel alloys, usually castings.

ECONOMIZERS

Economizers are used to increase the temperature of feed water before it enters the boilers, by absorbing heat from the flue gases leaving the boiler. Especially at high steam pressures, the flue gases leave the boiler at temperatures too high to escape up the stack without considerable loss in efficiency. This situation cannot be avoided since the temperature difference between the gases and the steam or saturated water is too low economically to allow use of additional boiler heating surface. However, the feed water is at a lower temperature than the water in the boiler and thus permits enough temperature difference with respect to the flue gases to allow using an economizer.

Economizers consist of bundles of tubes arranged horizontally and connected to inlet and outlet headers to form a number of parallel paths for the water. The tubes forming such continuous circuits may be joined by U-bends, by flanged bends, or expanded into short forged junction boxes. Provision is made for inspection and cleaning. The tubes may be plain or have extended surface in the form of rings, gills, fins, or pegs manufactured so as to be integral with the tube or substantially so for heat-transfer purposes. The tube sizes most commonly employed are $1\frac{1}{8}$, $1\frac{1}{4}$, $1\frac{1}{2}$, and 2 in., measured on the outside diameter.

They are commonly fitted with soot blowers to clean the deposits from the gas side. The inside is cleaned by the same type of tube cleaner as is used in the boiler tubes. The widespread use of deaerating feed-water heaters and chemical treatment of boiler feed water has removed the corrosion troubles and attendant leakages previously experienced with economizers before the introduction of these advances in technique.

Boilers with economizers are shown in Figs. 2, 7 to 11, 22, and 23.

AIR HEATERS

Air heaters are generally used when multiplestage steam extraction from the turbine is employed for feed-water heating. Under such conditions the temperature of the feed water is so high that an economizer alone will not reduce the temperature of the flue gases sufficiently to attain the desired boiler efficiency. Further reduction in gas temperature is then achieved by absorbing the heat from the gases in the air required for combustion of the fuel. In many instances the economizer may be omitted altogether, only an air heater being employed to reduce the gases to a suitable temperature to meet the required efficiency.

Air heaters are nearly always of the tubular type, consisting of bundles of tubes disposed horizontally and expanded at the ends into vertical tube sheets. As commonly arranged, the hot flue gases pass upward over the outer surface of the tubes and the air makes two passes through the tubes in a substantially countercurrent direction. The most popular tube sizes are $1\frac{1}{2}$ and 2 in. O.D. Soot blowers and steam lances are used to keep the outer surfaces of the tubes clean.

Where boilers fitted with air heaters may be operated for extended periods at low rates of evaporation, as in port, poor combustion conditions together with the water vapor and sulfuric acid in the flue gases result in sticky deposits

TIME

Kinds of Time. Three kinds of time are recognized by astronomers, *viz.*, sidereal, apparent solar, and mean solar time. The **sidereal day** is the interval between two consecutive *transits* of some fixed celestial object across any given meridian, or it is the interval required by the earth to make one complete revolution on its axis. This interval is constant, but it is inconvenient as a time unit because the noon of the sidereal day occurs at all hours of the day and night. The **apparent solar day** is the interval between two consecutive transits of the sun across any given meridian. On account of the variable distance between the sun and earth, the variable speed of the earth in its orbit, the effect of the moon, etc., this interval is not constant and consequently cannot be kept by any simple mechanism, such as clocks or watches. To overcome the objection noted above, the **mean solar day** was devised. The mean solar day is the length of the average apparent solar day. Like the sidereal day it is constant, and like the apparent solar day its noon always occurs at approximately the same time of day. By international agreement, beginning Jan. 1, 1925, the astronomical day, like the civil day, is from midnight to midnight. The hours of the astronomical day run from 0 to 24, and the hours of the civil day usually run from 0 to 12 A.M. and 0 to 12 P.M. In some countries the hours of the civil day also run from 0 to 24.

The Year. There are three different kinds of year used, the sidereal, the tropical, and the anomalistic. **The sidereal year** is the time taken by the earth to complete one revolution around the sun from a given star to the same star again. Its length is 365 days, 6 hours, 9 minutes, and 9 seconds. The **tropical year** is the time included between two successive passages of the

of combustible material on the outer surface of the air-heater tubes. These deposits are usually heavier on the tubes where the flue gases leave the air heater and where the temperature of the entering air is lowest. When the boilers are operated at higher rating, the combustible matter deposited on the tube is likely to become ignited and may result in complete destruction of the air heaters. Therefore, care should be exercised to clean air heaters after extended periods of boiler operation at lower rates.

Boilers having air heaters are shown in Figs. 4 and 12.

COMBUSTION CONTROL

Automatic combustion-control equipment is intended to supply fuel and air to the boilers in proportion to the steam demand, to regulate the draft, and to divide the steam load properly among the boilers. Since fluctuations in steam demand are immediately reflected in corresponding fluctuations in the pressure in the main steam header, it is usual to employ a master controller, responsive to such pressure fluctuations, which sets up and transmits impulses to the various actuating elements controlling the supply of fuel and air to the boilers. Provision is made so that manual control of the boilers may be resorted to if desired.

Such control assures proper proportioning of air and fuel in following load fluctuations with improvement in efficiency and avoidance of smoke. The actuating medium is usually air, although some systems utilize oil or electricity.

CODES AND RULES

The design of pressure parts of boilers for installation in merchant tonnage is governed in the interests of safety by various codes and rules, such as "Marine Engineering Regulations and Material Specifications" of the Merchant Marine Inspection Division of the U.S. Coast Guard, "Rules for the Classification and Construction of Steel Vessels" of the American Bureau of Shipping, "Rules and Regulations" of Lloyd's Register, of Shipping, and occasionally by the "Rules for the Construction of Power Boilers" of the American Society of Mechanical Engineers. These regulations also set forth minimum clearances to be observed in arranging the boilers in the fireroom space. Boilers for use in combat ships are designed in accordance with the provisions of the "General Specifications for Machinery" of the Bureau of Ships of the Navy Department.

Care should be exercised in the use of these regulations to be assured that the latest amendments are at hand.

CAPACITY AND RATING

When steam boilers were employed principally to drive steam engines, it was convenient to rate them in horsepower. Tests at the Centennial Exposition in 1876 determined that an average engine required approximately 30 lb steam per hr to produce 1 hp, hence it was recommended that a boiler horsepower be defined as the evaporation of 30 lb water per hr at 70 psi gage from feed water at 100 F. This unit of capacity was later changed to an equivalent evaporation of 34.5 lb per hr "from and at 212 F." Based on the latest steam table values, this represents 33,475 Btu per hr. The term

from the storage bunkers by a transfer pump and the oil is heated by a series of steam grids at various levels which cause any water to precipitate, 24 hr usually being allowed for this process. The settling tanks are located so that the suctions from them are above or nearly level with the fuel-oil service pumps which deliver to preheaters, thence to the burners. Suction and discharge strainers are provided. Each tank should have a capacity such as to operate the vessel at full power for 30 hr.

Atomizers. A burner for fuel oil consists essentially of two parts: the atomizer for converting the stream of solid fuel oil into finely divided particles, and the air register for effectively introducing among the finely divided

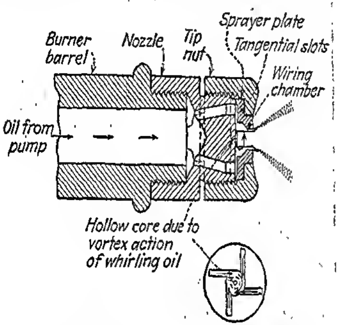

FIG. 28.—Straight pressure or mechanical atomizer.

particles of fuel oil the air required for combustion. Several means may be employed. There are four types of atomizers in common use as follows:

1. Straight pressure or mechanical atomizer (Fig. 28).
2. Straight pressure atomizer with return flow of fuel oil—wide range atomizer (Fig. 30).
3. Steam atomizer (Fig. 32).
4. Rotary-cup (spinning-cup) atomizer (Fig. 34).

The atomizing principle used in the mechanical atomizer, shown in Fig. 28, consists of delivery of several streams of fuel oil at high velocity through passages discharging tangentially into a small cylindrical chamber that verges into a cone with a discharge orifice at its apex through which the oil is sprayed into the boiler furnace. To obtain the high velocity required to produce a suitably fine spray, pressures of 75 to 300 psi are used, and the fuel oil is heated to a temperature where its viscosity will be 150 SSU. The centrifugal and axial forces set up in the chamber result in the production of a hollow conical spray. The designer can achieve considerable latitude in regard to spray angle and fineness of atomization by changing the shape and dimensions of the chamber, the number and dimensions of the tangential passages, the ratio of their total area to the area of the outlet orifice, etc.

"boiler horsepower" is now obsolete and is employed only rarely in reference to certain conventional boilers of small capacity.

The factor of evaporation is equal to the enthalpy (heat content) of 1 lb steam at the stated conditions of pressure and total temperature less the enthalpy of the liquid at feed temperature, divided by 970.3 (the latent heat of evaporation at 212 F).

At one time it was customary to rate boilers on the basis of a certain number of square feet of heating surface per boiler horsepower (10 sq ft was customary for stationary boilers), but as boiler designs and firing methods improved and as water-cooled furnaces, superheaters, economizers, and air heaters came into use, it became apparent that boilers could develop several times the capacity based on such a concept. As a result, this practice of rating fell into disuse, because it is meaningless. In the modern steam-generating unit the heat absorbed by the boiler becomes proportionately a smaller part of the total as waterwalls, superheater, economizer, and air heater are incorporated into the design, and as higher steam pressures are used.

A modern boiler, when producing its proportionate share of the steam quantity required to develop the rated shaft horsepower of the propulsion equipment at the normal speed of the ship, is considered to be operating at its normal or full power rating. Other rates of steam output are customarily stated in terms of this nominal capacity.

EFFICIENCY

The efficiency of a boiler or steam-generating unit is the ratio of the heat absorbed by the steam produced to the heat represented by complete combustion of the fuel fired. It is customary in American practice to use the high heat value of the fuel. European practice employs the low heat value. Since it is well-nigh impossible to determine or segregate the actual efficiency of a boiler only, it is usual in commercial practice to include boiler and furnace efficiency together.

The efficiency of a steam-generating unit may be found by accurate determination of the weight of steam produced or feed water used and of the fuel fired, or by careful measurements of the heat losses and a heat balance.*

With a knowledge of the composition of the fuel being burned, the composition of the products of combustion, *i.e.*, the flue gases, provides a check on how well combustion of the fuel is taking place. The analysis of the flue gases to determine their composition is customarily carried out in an Orsat apparatus. This consists essentially of a burette and three pipettes. The burette is graduated for measuring the sample of gas and the quantities of the gaseous constituents removed in the pipettes. The three pipettes contain solutions of caustic soda or caustic potash to absorb CO_2, cuprous chloride to absorb CO, and pyrogallol to absorb O_2.

Thus the Orsat apparatus provides the percentages by volume of CO_2, CO, and O_2 in the flue gases. The N_2 is assumed to be the balance. Any SO_2 appears as CO_2 but for fuels used aboard ship this slight discrepancy may be disregarded for all practical purposes.

---

* For complete details of efficiency tests the reader is referred to the Test Code for Power Boilers of the A.S.M.E. or the *Trans. Amer. Soc. Naval Engrs.*, 172–176, 1942; 53; 724–734, 1941; 54.

The capacity for any given orifice size varies closely with the square root of the supply pressure. With the pressure range noted, the operating range of

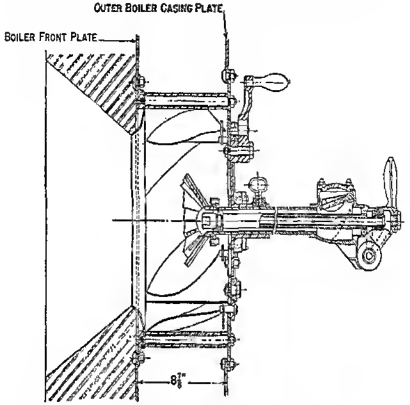

FIG. 29.—Assembly of Todd "Hex-Press" register with "Vee-Cee" atomizer.

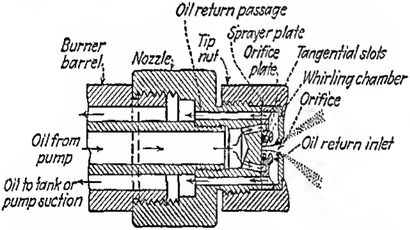

FIG. 30.—Return-flow atomizer, pressure type—Todd Combustion Equipment.

this type of atomizer is limited to a quantity ratio of 1:2. All the oil entering the chamber is discharged into the furnace.

These values provide a measure of the completeness of combustion. Satisfactory combustion of fuel oil can be obtained with 15 to 20 percent excess air and of coal on stokers with 35 to 40 percent excess air. Black smoke is ordinarily due to low excess air but may be produced with high excess air due to improper adjustment of burners and air leakage. With black smoke the Orsat analysis of the gases will usually show high CO_2, low O_2, and the presence of CO if the burners are improperly adjusted. If there is air leakage, the Orsat analysis will then show low CO_2, high O_2, and some CO. White smoke is an indication of too much excess air. Under these conditions the Orsat analysis will show low CO_2, high O_2, and no CO. With the correct quantity of air for the fuel and proper burner adjustment the stack emission should be a faint brown haze and the flue gases should contain no CO.

With the composition of the fuel and the flue gas known, it is possible to calculate various heat losses by the following relations. Sample calculations are included based upon the average analysis for a fuel oil (p. 1006).

Example. Assumed flue gas analysis, percent by volume (from Orsat):

CO_2	13.5
CO	0.2
O_2	3.4
N_2	82.9
	100.0

t_g = temperature, deg F, of flue gases leaving steam-generating unit; say 345 F
t_a = temperature, deg F, of air supply to steam-generating unit; say 100 F.

1. Weight of dry flue gases, lb per lb fuel:

$$W_g = \frac{11CO_2 + 8O_2 + 7(CO + N_2)}{3(CO_2 + CO)} \text{ (carbon burned, lb per lb fuel)}$$

$$W_g = \frac{11(13.5) + 8(3.4) + 7(0.2 + 82.9)}{3(13.5 + 0.2)} \text{ (0.864)} = 15.9 \text{ lb dry gas per lb oil}$$

2. Weight of water from combustion of hydrogen in fuel, lb per lb fuel:

$$W_h = 9 \times \text{(hydrogen in fuel, lb per lb fuel)}$$
$$9(0.107) = 0.963 \text{ lb water per lb oil}$$

3. Dry air, lb per lb fuel $= W_g + W_h - (1 - \text{refuse, lb per lb fuel})$

$$W_a = 15.90 + 0.96 - 1 = 15.86 \text{ lb dry air per lb fuel}$$

4. Weight of water vapor in air for combustion, lb per lb fuel:

$W_v = W_a \times$ (water vapor in air, lb per lb air) at 100 F dry bulb and 37 percent relative humidity, read from psychometric chart, water vapor in air = 0.015 lb per lb air

$$W_v = 15.86 \times (0.015) = 0.24 \text{ lb water vapor in air per lb fuel}$$

5. Weight of wet products of combustion, lb per lb fuel:

$$W_p = W_g + W_h + W_v$$
$$W_p = 15.9 + 0.96 + 0.24 = 17.1$$

Mechanical atomizers with return flow, illustrated in Fig. 30, have been developed to secure an increase in operating range. This is accomplished

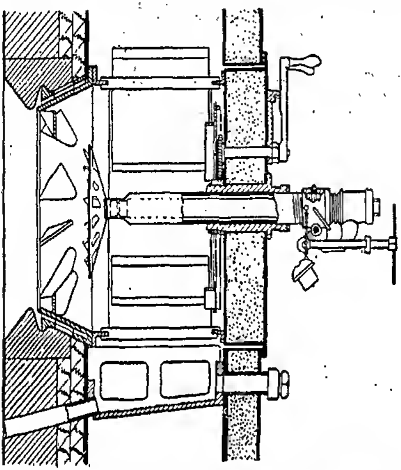

Fig. 31.—Babcock and Wilcox "Decagon" burner and register.

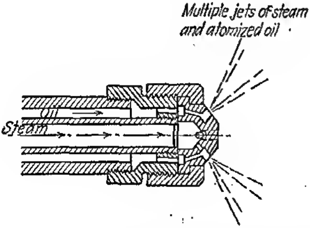

Fig. 32.—Steam atomizer.

either by supplying the whirling chamber with a quantity of fuel oil greater than that to be discharged and returning the excess to the supply pump suction or by varying the area of the tangential passages into the whirling

6. Excess air, percent above that required for complete combustion (an item not directly required for the heat balance, but of interest as indicating quality of operation):

$$X = 100\frac{(O_2 - 0.5CO)}{0.264N_2 - O_2 + 0.5CO}$$

$$X = 100\frac{[3.4 - 0.5(0.2)]}{0.264(82.9) - 3.4 + 0.5(0.2)} = 18 \text{ percent excess air}$$

Heat losses	Btu per lb fuel	Per cent
1. Loss due to sensible heat in dry flue gases: Loss $= 0.24W_g(t_g - t_a)$ $= 0.24 \times 15.9(345 - 100)$ Loss $= 935$ Btu per lb fuel or $\frac{935 \times 100}{18{,}500} = 5.05\%$	935	5.05
2. Loss due to heat in water formed by combustion of hydrogen in fuel: Loss $= W_h(1089 + 0.46t_g - t_a)$ for $t_g < 575$ F or $= W_h(1066 + 0.5t_g - t_a)$ for $t_g > 575$ F $= 0.963[1089 + 0.46(345) - 100]$ $= 0.963(1148)$ Loss $= 1110$ Btu per lb fuel, or $\frac{1110 \times 100}{18{,}500} = 6.00\%$	1110	6.00
3. Loss due to evaporating and superheating moisture contained in the fuel (may be neglected for oil): Loss $= (W_m$, lb moisture per lb fuel$)(1089 + 0.46t_g - t_a)$ for $t_g < 575$ F $= (W_m$, lb moisture per lb fuel$)(1066 + 0.5t_g - t_a)$ for $t_g > 575$ F Loss $= 0.003 \times 1148 = 3.45$ Btu per lb fuel; neglect		
4. Loss due to superheating water vapor in air for combustion: Loss $= 0.47W_v(t_g - t_a)$ $= 0.47 \times 0.24(345 - 100)$ $= 28$ Btu per lb fuel or $\frac{28 \times 100}{18{,}500} = 0.15\%$	28	0.15
5. Loss due to incomplete combustion of carbon, *i.e.*, burning carbon to CO instead of CO_2: Loss $=$ (carbon burned per lb fuel) $\left(\frac{CO}{CO_2 + CO}\right)$ 10,160 $= 0.864\left(\frac{0.2}{13.5 + 0.2}\right)$ 10,160 $= 128$ Btu per lb fuel, or $\frac{128 \times 100}{18{,}500} = 0.7\%$ (This loss is avoidable, especially with oil firing, and should be eliminated by proper firing conditions)	128	0.7
6. Loss due to unconsumed carbon in refuse (negligible for oil): Loss $=$ (refuse, lb per lb fuel $-$ ash, lb per lb fuel) 14,600		
7. Losses due to radiation, and to unburned hydrocarbons, usually known as unaccounted for loss. These can only be determined by subtracting from the heat input in the fuel the sum of the calculated losses above and the heat absorbed by the steam		

TYPICAL HEAT BALANCES

Typical efficiency curves of modern boilers for merchant and naval combat vessels are shown in Fig. 25. Typical heat balances for oil-fired boilers in merchant and naval vessels are shown in the table on page 1002.

chamber by an adjustable sleeve or plug. By either method the object is to maintain high enough velocity through the tangential passages for a good degree of atomization. With the return-flow principle, the range can be increased to as high as 1:10, depending upon furnace conditions and the maximum rate of firing. In the movable-plug design, the range can be increased to 1:4.

As the name implies, the steam atomizer employs steam as the atomizing agent. This steam atomizer is usually constructed so that a number of steam jets can be directed to impinge on an equal number of small streams of solid oil as shown in Fig. 32. The impingement breaks up the oil to

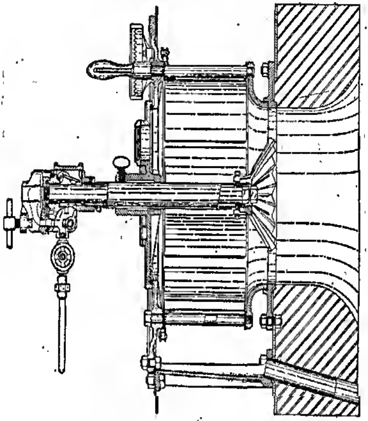

Fig. 33.—Peabody type ML burner and register.

produce an effect similar to the hollow cone-shaped spray obtained with the two types of straight pressure atomizers. In this type of atomizer, it is necessary to preheat the oil to a temperature high enough to reduce the viscosity to 300 SSU. The oil-supply pressure may be varied from 5 to 300 psi. The steam pressure relative to the oil pressure is maintained at a constant differential of about 10 psi by use of a differential valve. A flow ratio of 1:10 may be realized. There has been no widespread application of this type of atomizer on board ship. Many operators object to the steam loss, especially where it must be made up by evaporation.

The rotary-cup atomizer consists primarily of a cup shaped like the frustum of a cone and rotating at about 3,400 rpm. Oil at 300 SSU is delivered into

at high velocity parallel to the axis of the cup. This air blast breaks up the film of oil, deflecting it into a hollow cone-shaped spray. Figure 34 shows the arrangement of a rotary-cup atomizer.

	Merchant service, %	Naval service, %
Loss due to:		
Moisture from air	0.15	0.20
Moisture from hydrogen in fuel	6.00	6.25
Sensible heat in dry gas	5.05	8.30
Radiated and unaccounted for	1.80	1.00
Total losses	13.00	15.75
Efficiency	87.00	84.25
Total	100.00	100.00

HEAT TRANSMISSION AND FLOW RESISTANCE

Heat Transmission. Heat from the products of combustion is transferred to the absorbing surfaces of the boiler unit by radiation and by convection. Luminous radiation accounts for most of the heat absorbed by the surface in the furnace. In the surface beyond the furnace most of the heat is absorbed by convection.

Furnace Heat Absorption. Some of the more important factors affecting the rate of heat absorption in a furnace are the type of fuel, the method of burning the fuel, the rate of heat input to the furnace, the furnace construction, and the condition of the absorbing surfaces.

The chemical analysis of the fuel determines the combustible constituents, the thermal energy available, and the composition of the products of combustion including water vapor. The method of burning the fuel, which is dependent upon the fuel's physical properties, influences the amount of excess air required for complete combustion. The amount of heat available is dependent primarily upon the firing rate but is affected also by the excess of combustion air and its temperature. All these factors affect the mean temperature of the luminous radiating gases which influences to a great extent the rate of heat absorption.

The radiating length of the luminous furnace gases is dependent upon the size and shape of the furnace. The proportion of radiant-heat-absorbing surface to refractory surface is an important factor influencing the rate of furnace heat absorption. Clean surfaces absorb more heat than slagged or dirty surfaces.

Rate of Radiant-heat Absorption. A correlation of actual data obtained with various furnace designs burning different fuels under varied combustion conditions allows an estimation of the rate of radiant heat transmission in a furnace under specified conditions. This rate may be expressed as follows:

$$Y = \frac{X}{1 + \frac{A}{K}(X)^n}$$

where Y = 1000 Btu absorbed per hr per sq ft effective projected radiant heating surface

X = 1000 Btu available per hr per sq ft effective projected radiant heating surface

A = lb combustion air per lb fuel

For the efficient combustion of the oil spray produced by any of the atomizers just described, it is necessary to employ an air register in conjunction with the atomizer. Air registers are designed so that they may be adapted to the type of draft under which the boiler unit is operated, such as forced draft, induced draft, or natural draft. The direction and velocity of the air supply are controlled by the register. The atomizer is so located that it will project the finely divided particles of oil along a path that will be intercepted by the air stream in such manner as to produce an intimate mixture of air and oil. The rapidity of combustion is affected by furnace temperature and dimensions, quality of atomization, velocity of air flow through the register, and temperature of the combustion air. Views of atomizers in air registers are shown in Figs. 29, 31, and 33.

A number of atomizers and registers, or oil burners, are applied to a furnace to obtain the desired quantity of oil with proper atomization and without requiring excessive air pressure.

Viscosity. On installations using straight-pressure or return-flow atomizers it is important that the operator know the viscosity of the oil as this determines the temperature to which it should be preheated in order to reduce its viscosity sufficiently to obtain proper atomization. The graph in Fig. 35 shows the effect of temperature on viscosity and, as there are several methods of calibrating viscosity, an approximate relation between the various methods is given in the accompanying table.

Approximate Relation between Engler Degrees, Saybolt and Redwood Seconds, at the Same Temperature

DRAFT

Forced Draft. The closed fireroom into which the forced-draft blower discharges directly and which is entered through an air lock is not used in modern ships. This arrangement is now superseded by an open fireroom

K and n = constants depending primarily upon type of fuel, method of burning the fuel, and size, shape, and construction of furnace. For marine boiler furnaces fired with fuel oil, the value of K is about 100 and of the exponent n about 0.45

The approximate trend of this relation for an average marine boiler furnace when burning fuel oil is shown by Fig. 26. With the amount of available heat known, the absorption rate may be determined from this curve. By deducting the quantity of heat absorbed from that available, the amount remaining in the combustion gases may be ascertained. From this value and the weight of gases the sensible heat in the gases, and from it the gas temperature leaving the furnace, may be calculated.

Convection-heat Transfer. To determine the heat absorbed by the surfaces beyond the furnace as well as the gas temperature drops in each it is necessary to evaluate the convection heat-transfer coefficients existing in the boiler banks, the superheater, and the heat-recovery equipment. These coefficients depend principally upon the gas velocity, the gas temperature, and the size and arrangements of the tubes. The transfer rate coefficient may be determined from an expression having the following form:

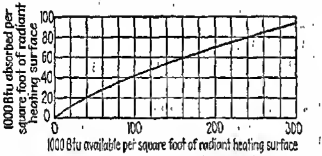

FIG. 26.—Typical curve showing ratio of heat absorbed to heat available in oil-fired furnace.

$$R = \frac{CKG^n}{D^{(1-n)}}$$

where R = heat-transfer coefficient, Btu/(hr)(sq ft)(deg F) logarithmic mean temperature difference
C = a constant
K = a variable depending the physical properties of the gas. These physical properties include the thermal conductivity, the absolute viscosity, and the specific heat
G = mass flow of the gas, lb per hr per sq ft minimum free area normal to the gas flow
D = tube diameter, ft
n = an exponent varying from 0.5 to 0.8 depending the type of flow and tube arrangement

Gas Temperature Drop. The amount of heat absorbed may be expressed by the following relation:

$$Q = R \times S \times \theta_m$$

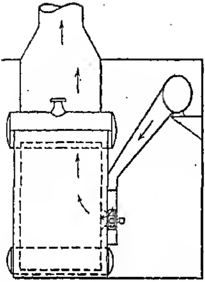

FIG. 36.—Forced draft direct from blower to double casing enclosing air registers.

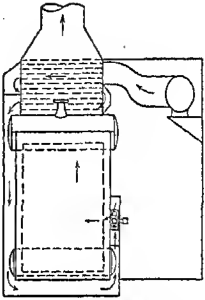

FIG. 37.—Same as Fig. 36 but with air heater.

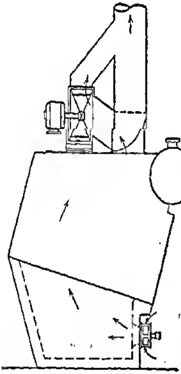

FIG. 38.—Air for combustion supplied by induced draft.

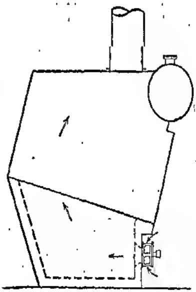

FIG. 39.—Air for combustion supplied by natural draft.

where Q = heat absorbed, Btu per hr
R = heat-transfer coefficient, Btu/(hr)(sq ft)(deg F)
S = effective heat-absorbing surface, sq ft
θ_m = logarithmic mean temperature difference, deg F

The quantity of heat absorbed is also equal to the product of the pounds of products of combustion per hour, W_g, the mean specific heat at constant pressure, C_p, and the difference between the temperature of the gases entering and leaving the heat absorbing surface, $T_1 - T_2$. The equation above, therefore, may be rewritten as follows:

$$T_1 - T_2 = \frac{R \times S \times \theta_m}{W_g \times C_p}$$

For a marine oil-fired boiler unit similar to that shown in Fig. 7, using both an economizer and an air heater to recover heat from the combustion gases, the gas temperatures throughout the unit are shown in Fig. 27. For detail information on rates of heat transfer, reference should be made to pp. 384 to 411.

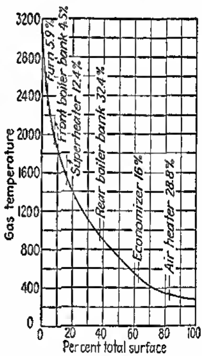

FIG. 27.—Typical curve showing distribution of heat-absorbing surface.

Fluid Flow Resistances. Resistance to flow is caused by the friction between the flowing fluid and the bounding surfaces, by change of direction such as bends and turns, and by enlargements and reductions in cross-sectional area through which flow is taking place. Frictional losses for flow inside of a tube, pipe, or duct are determined experimentally and are found to depend primarily upon the length, diameter, and velocity. The other losses are found to depend primarily upon velocity.

Steam- and Water-pressure Losses. To determine the pressure loss of water flowing through an economizer or steam through a superheater, it is necessary to determine the frictional losses. Usually it is possible to express the entrance, exit, and bend losses as equal to a certain number of tube diameters or equivalent to a fixed number of feet of straight tubing. With this method the pressure loss may be calculated as follows:

$$\Delta p = \frac{kfLvG^2}{d}$$

where Δp = pressure loss, psi
k = constant
f = friction factor (dimensionless) depending upon Reynolds number
L = equivalent length of tubing, ft

with a modern ventilation system. The forced-draft blower discharges directly to a wind box surrounding the burners on the front of the boiler as in Fig. 36. This may be varied, depending upon the design of the boiler, so that the wind box also surrounds the furnace or even the entire boiler as in Fig. 37. In other words, the furnace portion of the boiler setting, or the entire boiler, may be double cased, with wind-box air pressure in the casing. Such designs preclude the escape of flue gases into the fireroom space. Such boilers operate entirely under forced draft. This arrangement is widely predominating in both merchant and naval tonnage.

Induced draft (Fig. 38). In this arrangement the stack induction is augmented by a blower interposed between the boiler outlet and the stack. The blower exhausts the combustion gas from the boiler and discharges into the base of the stack. The entire system is always under a negative pressure. It is not frequently used in present-day practice because of the large blower capacity required and mechanical difficulties due to temperature of the stack gases.

Natural draft (Fig. 39). In this arrangement the stack induction, created by the difference in density between the column of hot gas and the outside atmosphere, is used to draw air through the burner air registers into the furnace. Changes in wind direction and velocity, changes in differential between stack gas and outside atmospheric temperature, and changes in firing rate all affect this natural draft arrangement, and the maximum firing rate available is always limited to the stack capacity. Owing to the greatly increased capacity at which present-day boilers are operated this type has practically disappeared.

COAL FIRING

Some special coastal and harbor craft on the East Coast nevertheless use coal, generally anthracite since it is cleaner and does not smoke. Many foreign vessels also operate on coal. If supplied at East Coast ports, low- and high-volatile bituminous coals from Pennsylvania, West Virginia, Virginia, and Eastern Kentucky are used. These are high-grade coals, the usual proximate analyses of which are as follows:

	Low-volatile bituminous	High-volatile bituminous	Anthracite
Moisture, %	2.6	3.0	5.5
Ash, %	5.9	6.2	10.5
Fixed carbon, %	73.7	57.0	80.0
Volatile matter, %	17.8	33.8	4.0
Sulfur, %	0.9	1.3	0.7
Heating value, Btu per lb (as received)	14,300	13,800	11,200

On the Great Lakes nearly all ships burn coal. Here coal enjoys a price differential over fuel oil owing to the expensive transportation charges for the latter. Furthermore, many of these ships transport coal or are owned by interests closely allied with the coal-producing industry.

With coal as fuel, two analyses are commonly used for practical purposes; the proximate and the ultimate, as well as the heating value. The proximate analysis generally consists of the relative amounts of (1) water or moisture, (2) volatile matter including gases and vapors, (3) fixed carbon, (4) ash or

v = specific volume of the fluid, cu ft per lb
G = mass flow of the fluid, lb per hr per sq ft of flow area
d = inside diameter of tube or pipe, in.

The water-pressure loss at normal power through the economizer of the boiler unit similar to that shown in Fig. 7 is about 5 psi, whereas the steam-pressure loss through the superheater shown is approximately 20 psi.

Resistance to Flow of Air and Gas. To obtain the frictional resistance of air or gas flowing through heating surfaces such as air-heater tubes or through ducts, casings, etc., the foregoing formula may be used with a consistent system of units. Usually the frictional loss for the straight portion of pipe, tube, or duct is used for the length (L), and the losses due to bends and to changes in cross-sectional area are calculated separately. These latter losses may be expressed as a fractional portion of a velocity head.

In calculating the resistance to flow over the banks of tubes that form the different convection heating surfaces of the boiler unit, the losses due to changes in flow area and direction are the most important. For practical purposes these are considered as one loss. This loss may be determined as follows:

$$\Delta p = \frac{kNTG^2}{10^{12}}$$

where Δp = air-pressure loss or draft loss, wg.
k = a constant depending on tube arrangement and type of heating surface, and ranges between 1.5 and 4.5, approximately
N = number of restrictions that air or gas must pass over
T = absolute temperature, deg R
G = mass flow of air or gas, lb per hr per sq ft of minimum free area normal to the gas flow

The air resistance through the burner registers is determined from standard curves based on actual test results with each specific type of burner. The correct evaluation of this loss is important since it accounts for as much as 50 percent of the total air and gas resistance.

For the boiler unit similar to that shown in Fig. 7, the air and gas resistances at normal power in inches of water are as follows:

Air resistance through air heater	1.0
Air resistance through duct from air-heater outlet to burners	0.2
Air resistance through burner registers	1.3
Gas resistance through boiler and superheater	0.3
Gas resistance through economizer	1.2
Gas resistance through air heater	1.2
Total air and gas resistance	5.2

For detail information on flow of fluids reference should be made to pp. 244 to 281 and 353 to 360.

FUELS

Steam-propelled ships generate steam by burning fuel oil or coal. Naturally, to secure the utmost in economy of operation careful consideration must be given to efficient combustion in the restricted furnaces available aboard ship. Unless this is done, losses of appreciable magnitude even extending beyond the furnaces will result.

mineral impurities. The sum of the percentages of each of these items totals 100 per cent for the coal in the "as received" state, *i.e.*, as sampled. The percentage of sulfur present is generally reported separately.

The ultimate analysis of coal is made up of the percentages of carbon, hydrogen, sulfur, oxygen, nitrogen, and ash, based on the dry coal, the sum of which is equal to 100 per cent. If based on the "as received" sample, the hydrogen and oxygen of the moisture are included in the hydrogen and oxygen of the dry sample. The ash content is the same as in the proximate analysis. Reference should be made to A.S.T.M. for the standard laboratory methods for determining the proximate and ultimate analyses of coal.

An ultimate analysis may be approximated from the proximate analysis of a coal.

In proximate analysis, the combustible = volatile matter + fixed carbon = coal as received − moisture and ash. Let V, H, C, and N be, respectively, the percentage by weight of volatile matter, hydrogen, volatile carbon, and nitrogen in the combustible. Then $H = V\{[7.35/(V + 10)] - 0.013\}$, which is accurate for American coals to about ±2 percent, approximately, by the following formulas:

$$C = 0.9(V - 10) \text{ for semianthracite}$$
$$C = 0.9(V - 14) \text{ for bituminous and semibituminous}$$

With anthracite, the standard methods of analysis usually show total carbon less than fixed carbon, because the "fixed carbon" contains other elements also.

Sulfur in coal directly increases the value of V; values of C calculated as above will be too high, approximately, by the sulfur content of the combustible.

The nitrogen (coming off in the volatile matter) may be calculated with an accuracy of ±0.5 percent by the formulas:

$$N = 0.07V, \text{ for anthracite and semianthracite}$$
$$N = 2.10 - 0.012V, \text{ for bituminous and lignite}$$

The heating value of fuel, also known as the calorific value, is the amount of heat developed by complete combustion of a definite quantity in an atmosphere of oxygen in a bomb calorimeter under a standard set of conditions. For complete details reference should be made to A.S.M.E. Power Test Codes. The value thus obtained is the high heating value at constant volume and is generally used in American practice. In European practice the low heating value is more generally employed. This is derived from the high heating value by deducting the heat of vaporization of the moisture in the fuel including the moisture formed when hydrogen is burned.

The high heating value of coal may be determined approximately by computation by Dulong's formula:

$$\text{Btu per lb} = 14{,}544C + 62{,}028\left(H - \frac{O}{8}\right) + 4050S$$

This formula employs the high heating values of the constituents found in the ultimate analysis; thus C, H, O, and S are the weight fractions from that source. The heating value of coal may be indicated on different bases, such as "as received," "dry," or "ash and moisture free."

The choice of either fuel oil or coal for merchant ships is practically entirely one of economics and availability. With oil, vessels may be fueled in much shorter time than with coal, thus reducing the time in port required for this function. This is important where ships operate on short-time turn-around, such as passenger ships. It also is becoming of increasing importance to merchant ships as improvements in cargo-handling facilities are receiving greater attention. Furthermore, fueling operations and the transfer of the fuel oil from the point of storage to the ship may be performed mechanically instead of manually. These operations are cleaner than bunkering coal. Fuel oil may be stored in the double bottoms of the ships whereas the bunkers required for coal storage encroach on cargo or other valuable space. Fuel oil poses no ash disposal problem. Mechanical handling equipment for coal and ash may be used but it is expensive and somewhat bulky. Finally, since fuel oil weighs less per unit of heating value, less weight of oil need be carried for the same operating radius; also less operating personnel is required than with coal where manually fired and where trimming must be done by hand.

These advantages in favor of fuel oil act to offset the price advantage of coal that generally prevails at East Coast ports. At Gulf Coast and West Coast ports fuel oil is seldom competitive with coal owing to the distance coal must be transported as compared to the oil.

Fuel Oil. In view of the foregoing nearly all oceangoing American tonnage propelled by steam uses fuel oil. Out of the processes of refining crude petroleum for the purpose of obtaining its most valuable and volatile constituents, residues of somewhat varying characteristics remain. Often these residues are of such a nature that lighter distillates are necessarily blended with them to obtain a product with sufficient fluidity for practical handling. Such residual oils commonly bear the name of "fuel oil" or bunker-C oil.

An average analysis of commercial fuel oil is

Carbon, %	86.4
Hydrogen, %	10.7
Sulfur, %	1.5
Nitrogen plus oxygen, %	1.0
Water, %	0.3
Sediment, %	0.1
Btu per lb	18,500
Flash point, deg F	175 F
Fire point, deg F	225 F
Specific gravity	0.975

Tanks. Delivery of fuel oil to a vessel may be from a shore station or from a barge—usually the latter. The number and arrangement of bunkers will depend upon the designer's desire to use space without interfering with cargo storage and machinery spaces. However, the oil filling system should be arranged with overflows so that while bunkering it will be necessary for the operator to observe the level in only one or two tanks, either by direct soundings or by a gage.

Storage tanks are provided with steam heating coils to reduce the oil viscosity to a point where it is readily pumpable, and the condensate from these coils is trapped. Before reentering the boiler feed system this condensate should be inspected for the presence of oil resulting from leakage.

It is customary to provide two deep "settling" tanks to permit separating out any water that may be entrained with the oil. These are filled with oil

Hand Firing. Although stokers for firing coal aboard ship have been available for years and numerous installations have been made with an increasing tendency in this respect, nevertheless most coal-burning marine boilers are hand fired. This condition prevails, even though this method of firing is the least efficient and the hard manual labor involved makes it unattractive to skilled personnel.

The method employed in hand firing depends on the kind of coal used. With anthracite and other low-volatile coals, it is usual to spread the fresh fuel evenly over the fire; with high-volatile coal either alternate firing or the coking method is employed. The former involves adding "green" coal to only half the fuel bed at a time. This permits the incandescent fuel on the other half to burn the volatiles liberated from the fresh coal. Noncaking coals are best burned in this manner. The latter method, which is well suited to caking coals, involves placing the fresh coal at the front of the fuel bed and permitting it to coke. It is then pushed back over the entire surface.

Spreader Stokers. The spreader stoker has gained popularity principally for vessels on the Great Lakes and on inland waterways, where most of the coal-burning ships in this country operate. Applications have been made to water-tube boilers of both the sectional-header and bent-tube types and to Scotch boilers. A typical arrangement is shown in Fig. 40. It projects sized coal of about ¼ to ¾ in., together with the fines, through the front wall of the furnace usually by means of rotating paddles. Sometimes jets of air or steam are used. If the coal received is larger, crushers are installed to reduce the size so it may be properly fed and burned. Most of the fines are burned in suspension. The larger pieces of coal fall to the grate and are burned there. The grate may be either of the stationary or dumping type. The distributing mechanism is usually divided into units, each consisting of a hopper, a feeding and a distributing arrangement, and the drive. The drive may be individual or from a jackshaft. Some designs utilize alternate rows of right- and left-hand distributor blades to obtain more nearly equal distribution of the coal. The speed of rotation of the blades determines the distance to which the coal is spread. Air is supplied both under the grate and over the fire.

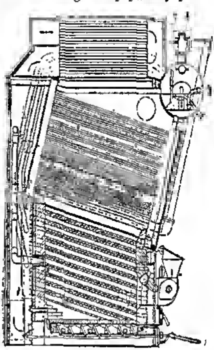

Fig. 40.—Sectional-header boiler equipped with spreader stoker.

High capacities are attainable with such stokers but, when forced, excessive quantities of cinder containing unconsumed carbon pass out of the furnace. In some installations provision is made for collecting this "carry-over" and returning it to the furnace, with resulting reduction of the loss from this source.

vernal equinox by the sun, and since the equinox moves westward 50."2 of arc a year, the tropical year is shorter by 20'23" in time than the sidereal year. As the seasons depend upon the earth's position with respect to the equinox, the tropical year is the year of civil reckoning. The **anomalistic year** is the interval between two successive passages of the perihelion, *viz.*, the time of the earth's nearest approach to the sun. The anomalistic year is only used in special calculations in astronomy.

The Calendar. The month depended originally upon the changes of the moon. The Mohammedan nations still use a lunar calendar with years of 12 lunar months, which contain 354 or 356 days in a specified cycle. According to their method of reckoning, the same month falls in different seasons and their calendars gain 1 year on ours about every 33 years. The **Julian calendar** (established 45 B.C. and now seldom used except in astronomy) discards all consideration of the moon and adopts 365¼ days as the true length of the year. The **Gregorian calendar**, now used in most of the civilized world, was adopted in Catholic countries of Europe in 1582 and in Great Britain and her colonies Jan. 1, 1752. For several years prior to the adoption of the Gregorian calendar the calendar year had begun on Mar. 25. When the change was made in Great Britain and her colonies, the year 1751 contained no January or February and no Mar. 1 to 24 inclusive. The calendar year 1751 was, therefore, short of a full year by 83 days. The calendar year 1752 was also 11 days short of a full year as the dates Sept. 3 to 13 inclusive, in that year, were dropped to correct the 11-day error that had accumulated during the use of the Julian calendar. The average length of the Gregorian calendar year is $365\frac{1}{4} - \frac{3}{400}$ days, or 365.2425 days. This is equivalent to 365 days, 5 hours, 49 minutes, 12 seconds. The length of the tropical year is 365.2422 days, or 365 days, 5 hours, 48 minutes, 46 seconds. Thus the Gregorian calendar year is longer than the tropical year by 0.0003 day, or 26 seconds. This difference amounts to 1 day in slightly more than 3,300 years, and can properly be neglected.

Standard Time. Prior to 1883, each city of the United States had its own time, which was determined by the time of passage of the sun across the local meridian. A system of standard time has been used since its first adoption by the railroads in 1883 but was first legalized on Mar. 19, 1918 when *Congress directed the Interstate Commerce Commission to establish limits* of the standard time zones. The United States, which extends from 65 to 125 deg west longitude, is divided into four zones each of 15 deg of longitude. The first or **Eastern zone** includes all territory between the Atlantic coast and an irregular line drawn from the United States-Canadian boundary just south of Drummond Island, through the Straits of Mackinac and the center of Lake Michigan, along the southern border of Michigan and the western border of Ohio, through the western part of North Carolina, and through central Georgia to the Gulf of Mexico at Apalachicola Bay, Fla. The time of this zone is that of the 75 deg meridian, which is 5 hr slower than Greenwich time. The second or **Central zone** includes all territory between the line mentioned and an irregular line drawn from the United States-Canadian boundary at the boundary line between North Dakota and Montana, along the western and southern borders of North Dakota to the Missouri River, through Phillipsburg, Kans., along the western boundary of Oklahoma and Texas to the Rio Grande River, and to the Mexican border. The time is that of the 90 deg meridian. The third or **Mountain zone** includes all territory between the last-named line and an irregular line

drawn from the United States-Canadian boundary at the northwest corner of Montana along the boundary between Montana and Idaho, the Salmon River, the western and southern borders of Idaho, through Salt Lake City, Utah, and Arizona to the United States-Mexican boundary on the Colorado River. The time is that of the 105 deg meridian. The fourth or **Pacific zone** includes all territory west of the last-named line to the Pacific coast except Alaska. The time is that of the 120 deg meridian. A fifth or **Alaska zone** includes Alaska only, the time being that of the 150 deg meridian. Standard time is uniform in each of these zones, and the time in one zone (except Alaska) differs by exactly 1 hr from the zone next to it. Four different times are used in Alaska: Pacific, 120°; Yukon, 135°; Alaska, 150°; and Western Alaska, 165°. In cities situated on the borderline of two zones, the standard time of the easterly zone is commonly used; in such cities when the time is given, it should be specified as Eastern, Central, etc. The *system of standard time has been adopted in almost all civilized countries* and now is used by ships on the high seas.

TERRESTRIAL GRAVITY

Standard acceleration of gravity is $g^0 = 980.665$ cm per sec per sec, or 32.1740 ft per sec per sec. This value g^0 is assumed to be the value of g at sea level and latitude 45 deg.

Acceleration of Gravity

(U. S. Coast and Geodetic Survey, 1912)

Latitude, deg	g		g/g^0	Latitude, deg	g		g/g^0
	Cm/sec²	Ft/sec²			Cm/sec²	Ft/sec²	
0	978.0	32.086	0.9973	50	981.1	32.187	1.0004
10	978.2	32.093	0.9975	60	981.9	32.215	1.0013
20	978.6	32.108	0.9979	70	982.6	32.238	1.0020
30	979.3	32.130	0.9986	80	983.1	32.253	1.0024
40	980.2	32.158	0.9995	90	983.2	32.258	1.0026

Correction for altitude above sea level: −0.3 cm per sec² for each 1,000 meters; −0.003 ft per sec² for each 1,000 ft.

SPECIFIC GRAVITY AND DENSITY

The **specific gravity of a solid or liquid** is the ratio of the mass of the body to the mass of an equal volume of water at some standard temperature. At the present time a temperature of 4 C (39 F) is commonly used by physicists, but the engineer uses 60 F. The specific gravity of **gases** is usually expressed in terms of hydrogen or air.

The **density** of a body is its mass per unit volume. If the gram is used as the unit of mass and the milliliter as the unit of volume, the figures representing the density are the same as the specific gravity of the body referred to water at 4 C as unity. The customary unit is pounds per cubic foot.

The specific gravity of liquids is usually measured by means of an hydrometer (see p. 250). Special arbitrary hydrometer scales are used in various

Since spreader stokers require generous furnace volume to secure proper length of flame travel and are sensitive to fuel and air control, they should be carefully regulated to avoid smoke. Air or steam jets directed across the furnace from the two front corners are effective in reducing smoke. Heat releases ranging from 20,000 to 35,000 Btu/(cu ft)(hr) are preferred for best results, but rates as high as 60,000 Btu/(cu ft)(hr) have been used successfully.

Colloidal Fuel. From time to time much emphasis seems to be placed on the use of colloidal fuel for firing boilers aboard ship. Colloidal fuel is a physical mixture of oil and coal. Usually, good grades of coal are selected. The coal must be pulverized exceedingly fine, so that 95 percent will pass through a 200-mesh screen. Even so, there is a tendency for the coal to settle out of the oil. Considerable work of an experimental nature with colloidal fuel has been carried out both aboard ship and ashore, but no widespread adoption has occurred. The abrasive character of the coal seems to have a detrimental effect on the pumps, pipe lines, valves, and burners. Furthermore, the ash deposited in the furnace and on the boiler surfaces enchances an already aggravating problem in the use of present fuel oils in maintaining furnace refractories and keeping the heating surfaces clean.

FEED-WATER AND BOILER-WATER TREATMENT

Feed water is the water fed to the boiler. Boiler water is that contained in the boiler. The latter, particularly in boilers operated at high rates of evaporation, contains many times the solids concentration of the former.

Feed water may be treated fresh water or condensate. Usually it is both, the former being known as "make-up." Although in naval practice it is considered essential to distill all make-up from sea water in order to be independent of shore water supplies, most vessels in merchant service depend on bunkering reasonably good fresh water in port. This is more economical and saves fuel. The troubles to be guarded against in the use of fresh water are scale, corrosion, foaming, and priming. The hard-scale-forming minerals are compounds of calcium, magnesium, and silica. Dissolved oxygen and acid water produce corrosion. Oil, grease, and certain organic matter are generally considered to contribute to corrosion as well as to priming and foaming.

The trend toward higher steam pressures and higher rates of evaporation in modern steam-generating units has introduced many new problems in feed-water and boiler-water treatment. Solutions of all these problems have been worked out, but it cannot be emphasized too strongly that the selection of the proper treatment should be placed in the hands of a competent chemist who specializes in this work.

Theory of Water Treatment. Waters may contain salts exhibiting two distinct solubility characteristics. Some show increasing solubility with increase of temperature; others show decreasing solubility with increase of temperature. The latter tend to become concentrated in excess of their saturation points in those parts of the boiler where evaporation is most rapid, *i.e.*, where the boiler surfaces are hottest, and deposit on such surfaces as crystals. The theory of water treatment is concerned with changing the solubility characteristics of such salts so as to increase their solubility with increasing temperature, or with changing them to other salts which will form sludges without tendency to adhere to the boiler surfaces and which will settle out in quiescent parts of the boiler where they may be blown off.

pressure cylinder is used, the value of C is the ratio of the combined volumes of the low-pressure cylinders to that of the high-pressure cylinder. Following are proposed values of R for maximum thermal efficiency in compound condensing engines with initial pressure P, pounds per square inch absolute.

P..........	90	120	150	180	200	220	250	275
R..........	10 to 13	11 to 14	13 to 17	16 to 21	19 to 23	22 to 27	25 to 32	28 to 36

P will range from 115 to 265, preferably not under 165 for condensing engines. Values of p, non-condensing, are from 15 to 17; condensing, 1 or 2, but preferably 1. Half the tabulated values of R may be used for compound non-condensing engines. Generally, in such engines, p_c is between 18 and 25 lb, increasing as P increases. The use of jackets warrants high values for R. High values are indicated when fuel is costly or the load is steady.

Clearances in compound engines are about the same, proportionately, as in simple engines. Usually $c_l > c_h$.

Diagram factors for compound engines expanding R times are about the same as those for simple engines with the $\sqrt{R}$ ratio of expansion (see p. 1023). High compression and excessive clearance reduce the value of f less than they do in simple engines. Superheat less than 150 F may be regarded as equivalent to jackets. Excessive terminal drop in the high-pressure cylinder (p. 1028) reduces the value of f. The use of a reheater between the cylinders is assumed; its omission may reduce the value of f by 0.05.

Size of Cylinder. Given f, p_{mh}, p_{ml},

$$H_i = (LNA_l f/16{,}500)[(p_{mh}/C) + p_{ml}] \qquad (12)$$

$$A_l = (H_i \times 16{,}500)/LNf[(p_{mh}/C) + p_{ml}] \qquad (13)$$

$$A_h = A_l/C$$

where A_h and A_l denote the net piston areas. (The strokes of the pistons are usually equal, although other obvious methods of arrangement are possible.) The quantity $[(p_{mh}/C) + p_{ml}]$ is the **mep referred to the low-pressure cylinder** ("equivalent mep"). This important design constant is usually between 23 and 31 lb in power-station practice. In Europe, it is about $1.2 + 0.05P$ for best thermal efficiency, increasing to $1.2 + 0.12P$ for best commercial efficiency, in condensing engines. The outputs of the two cylinders will have the ratio

$$(H_h/H_l) = (p_{mh}/Cp_{ml}) \qquad (14)$$

Note also that $2LN = S$. Values for L, N, and S are as given on p. 1024. Common values of p_{ml} in stationary practice are between 8 and 15; with the usual division of work and cylinder ratio, the corresponding values of $(p_{mh}/C + p_{ml})$ are from 24 to 32.

The receiver volume is usually 1.5 to 2 times the high-pressure cylinder volume. Large receivers make the engine sluggish in following load changes with fixed low-pressure cutoff.

When the receiver delivers part of its steam for heating or process work, the action is as suggested by the diagrams *habg*, *gmnef* (Fig. 3), and the mean effective pressure of the low-pressure cylinder becomes

$$p_{ml} = \frac{P_e}{C}(1 - x)\left(1 + \log_e \frac{C}{1 - x}\right) - p \qquad (15)$$

where x is the proportion of steam supplied to the high-pressure cylinder which is drawn off for heating. Equations (12) and (13) should then be used

Chemical Treatment. The chemicals commonly employed are soda ash, sodium phosphate, and, under certain conditions, colloidal compounds in combination with the other chemicals. Because of the rapid hydrolysis of soda ash in the boiler water, sodium phosphate is generally preferred to prevent scale and control alkalinity. This substance changes the calcium and magnesium carbonates and sulphates to the corresponding phosphates which precipitate as sludge. Phosphates do not form hard adherent scale and, if deposited, may be flushed out by a stream of water.

The phosphate may be used in the form of monosodium phosphate, disodium phosphate, trisodium phosphate, or sodium metaphosphate, depending on the alkalinity in the feed water. If the feed water contains excess alkalinity, monosodium phosphate is generally used to lower it. Monosodium phosphate has a tendency to deposit in the piping and equipment before reaching the boiler. Where its use is indicated, sodium metaphosphate may be used to avoid this trouble. It produces the same effect in the boiler, *viz.*, it breaks down into a monosodium phosphate, but the rate at which this reaction proceeds is slow enough so that it does not take place before reaching the boiler. Usually it is necessary to employ more than one form to secure excess phosphate for control of scale formation and excess alkali for control of alkalinity.

Condensate that contains only the small amount of impurities present from condenser leakage is usually treated within the boiler to neutralize any acids and to raise the pH value. Treatment with sodium phosphate renders harmless any calcium and magnesium compounds. Phosphate, except the metaphosphate, is always supplied directly to the boiler through a separate line. If added to the feed water, it causes deposits in the feed pump and feed piping.

Corrosion. Boiler corrosion is of three kinds: that due to acid, to oxygen, and to hot spots in areas of active heating surface.

Corrosion is generally controlled by maintaining the alkalinity of the boiler water above a pH value of 9.5 but not in excess of 11.0.

The water may be acid because of acids dissolved in it, or pure water may act as a weak acid. Treated water is usually alkaline but condensate, which is nearly pure water, usually requires treatment to render it alkaline. Phosphate fed into the boiler also affords certain protection against corrosion.

pH Value. This is an arbitrary symbol adopted to express the degree of acidity or alkalinity of a solution. It is the logarithm of the reciprocal of the hydrogen-ion concentration, in gram mols per liter at 71.6 F. A pH of 7 represents a neutral solution; lower values represent acidity, higher values alkalinity. Laboratory investigations have indicated that the minimum solubility of iron in distilled water occurs at a pH of 9.5.

Corrosion due to oxygen dissolved in the feed water is especially active at high pressures and temperatures. As little as 0.01 cc per liter of dissolved oxygen in the water of high-pressure boilers has been found to cause corrosion. Complete deaeration and chemical control are vital in high-pressure boiler operation.

Deaerating feed-water heaters have become an essential part of most modern high-pressure propulsion plants. Removal of oxygen by sodium sulfite is not advised as a substitute for deaeration and should be used only to remove the traces remaining from incomplete deaeration.

Compounds formerly were added to the feed water in an endeavor to remedy improper water conditions in boilers. These compounds were mix-

in design. A simple engine should be used if a large amount of low-pressure waste steam can be utilized.

Superheated Steam in Compound Engines. With superheat exceeding 150 F, Eqs. (10) and (11) are invalid. The curve abc (Fig. 3) may be represented by pv^n = const, the value of n being that given on p. 1025 for a simple engine.

Governing Compound Engines: High-pressure Terminal Drop. In early (Woolf) compound engines, without a receiver, the arrangement was necessarily either tandem or opposed and the low-pressure cylinder admitted steam throughout the full stroke. Present-day engines may have the pistons out of phase, the receiver and pipes storing steam between the cylinders; and the low-pressure cylinder works expansively while the division of work between the cylinders is controlled by variation of receiver pressure.

If an engine with any definite amount of terminal drop (*i.e.*, excess of terminal expansion pressure in the high-pressure cylinder above the receiver pressure) at normal load has a fixed point of low-pressure cutoff, increase of load will increase the receiver pressure and the proportion of work done by the low-pressure cylinder without changing the drop.

With variable low-pressure cutoff a later cutoff lowers the receiver pressure and increases the drop, without any appreciable influence on the output of the whole engine. The output of the low-pressure cylinder is decreased because of the reduced receiver pressure, in spite of its later point of cutoff. The output of the whole engine is increased by delaying high-pressure cutoff. The division of work between the cylinders may then be kept equal by also delaying low-pressure cutoff; but this will cause increased drop.

Whether any drop should be permitted at normal load is a controverted subject (see B. C. Ball, *Trans. A.S.M.E.*, **21**, p. 1002). There should be none in an engine intended for frequent overload conditions.

Factors beyond the Cylinder

Mechanical Efficiency. The power lost in friction, H_f, may be regarded as constant (see p. 1037), so that the brake horsepower, H_b, is $H_i - H_f$ at all loads. The mechanical efficiency at full load is

$$M = H_b/H_i = (H_i - H_f)/H_i$$

H_i being taken at full load. As the load increases, the **mechanical efficiency** steadily increases. At the Q proportion of full rated load, it is

$$M_1 = (Q + M - 1)/Q$$

The **commercial efficiency** of the engine is determined jointly by its thermal and mechanical efficiencies, and the most economical ratio of expansion is commercially somewhat less than that which gives highest thermal efficiency. From a standpoint of capacity alone, moreover, the maximum practicable value of R is determined by the expression

$$\frac{P}{R} - p = (1 - M)\left[\frac{P(1 + \log_e R)}{R} - p\right] \tag{16}$$

Values of M range from 0.82 to 0.97, tending to vary inversely with the initial pressure, the number of cylinders, and number of journals, and directly with the size of engine and the ratio of mean effective to maximum pressure. These variations are obscured by the factors of workmanship and lubrication; values for standard types of engine are variable within the above limits.

tures of common chemicals which the user confidently accepted as a cure-all for boiler-water troubles. With the development of modern water-treating theory and practice it has been found that there is no one compound universally applicable to all boiler conditions unless the source of the make-up and operating conditions are similar and closely controlled. Such a condition exists in the case of naval boilers. The U.S. Navy has carried out considerable research and as a result has developed a compound composed of 47 per cent anhydrous disodium phosphate, 44 per cent soda ash, and 9 per cent starch. This compound is used to adjust boiler-water alkalinity. It should be noted, however, that this compound was developed to meet the special conditions of naval boiler operation in which make-up is distilled from sea water.

It has been found that feed-water contamination from the types of tank coatings used in the bunker tanks may be more serious than condenser leakage. Serious attention should be given to the selection of coatings for this purpose.

The arrangement of the feed system and boilers should contain provision for sampling lines to provide feed-water and boiler-water samples that will be truly representative. Such sampling connections should have cooling coils so that no vapor or oxygen will be lost from the sample by flash. Sample lines of small diameter are preferred so that they may be thoroughly flushed without too much waste before securing the sample.

Test outfits have been developed for the use of the operating personnel in checking quality of the feed water and boiler water and for controlling the treatment. Such a kit should be provided aboard every ship. Nevertheless, periodic checks should be made from time to time by a qualified feed-water chemist.

Priming is the propulsion of water into the steam drum by extremely rapid boiling. It is spasmodic, in contrast to steady carry-over, and results in the entrainment of considerable moisture with the steam. It is usually caused by rapid pressure drop and sudden changes in water level, such as accompany rapidly fluctuating loads where the boiler drum is too small and hence the steam storage space or steam-disengaging surface is too limited.

BOILER CLEANING

Removal of Internal Deposits. Scale formation on the internal surfaces of boilers, waterfalls, superheaters, and economizers interferes with effective heat absorption of these surfaces. In boilers, waterwalls, and superheaters, especially where the rates of heat absorption are high, this condition is quite apt to result in overheated, bagged, or ruptured tubes, with resultant loss of the unit in outage and the expense of repairs. Such scale deposits are generally removed by rotating cutters or steel brushes driven by motor, air-, steam-, or water-powered. These devices, sometimes termed tube turbines, are designed to pass the bends customarily employed in the design of natural circulation boilers.

Methods of cleaning boilers chemically have been developed and have the possibility of saving considerable time compared to the mechanical tube cleaners. Chemical cleaning should be done only under supervision of reputable concerns which have personnel experienced in the work.

The method to be used will be governed by the composition of the scale. Some scales can be effectively removed by boiling out with a strong alkaline

STEAM-ENGINE ECONOMY

Variables Affecting Economy

Initial Pressure. The efficiency varies directly with the initial pressure. With *slight expansion, the variation is unimportant. At high ratios of expansion, high initial pressures have marked influence on efficiency.* The **ideal economies** of Tables 2 to 8, computed for cycles with incomplete expansion, illustrate these points. The results of varying initial pressure with superheated steam are shown in Tables 4 to 7. In condensing engines with superheat, high pressure is less important than in non-condensing engines.

High Steam Pressures. Higher efficiency of the steam-engine cycle can be obtained by increasing the temperature range. With fixed back pressure, higher steam pressures and temperatures are necessary. The practical limit of steam temperature today is about 750 to 800 F. A lubricating oil, having a flash point of about 650 F, will satisfactorily lubricate cylinders operating with steam at 800 F. Steam pressures up to 1,400 to 1,500 lb per sq in.

solution. Others require an acid solution containing an inhibitor to prevent active corrosion of the steel.

Acid cleaning requires use of a portable circulating pump and careful attention to venting of fumes to avoid toxic atmospheres in the fireroom.

Chemical cleaning is worthy of consideration as a method of cleaning boiler units installed with large economizers and superheaters which have a great number of tubes, usually with short bends.

Removal of External Deposits. Whether steam-generating units are fired by fuel oil or coal, the flue gases contain soot and other solid impurities present in the fuel. These materials are deposited in the furnace and on the outer surfaces of boiler tubes, superheater tubes, and economizer and air-heater tubes. They will also deposit on any ledges, although a properly designed boiler unit will have none of these. In zones of intense heat these deposits may even fuse to the surfaces. If not removed, such deposits, because of their definite insulating properties, will seriously interfere with *the transfer of heat* and *reduce the efficiency. If they become excessive,* the flue-gas passages are choked and require excessive draft and higher fan power. Removal of these deposits may be accomplished by a steam or air hand lance or by mechanical soot blowers. The latter are preferable.

A hand lance consists of a pipe of suitable length and diameter so it will pass between the tubes with one end flattened or nozzle-shaped and fitted with a length of hose to connect to a supply of steam or air. Inserted through openings provided in the setting, the force of the steam or air jet loosens the deposits, the fine particles being carried by the flue gases up the stack, the coarse ones falling into the furnace. This method is uncertain, dirty, tedious, sometimes hazardous, and, if steam is used, wasteful.

Such deficiencies are overcome by the use of mechanical soot blowers. As a result nearly all marine boilers now are so equipped. Mechanical soot blowers consist essentially of tubes, usually 1½ or 2 in. O.D., fitted with nozzles, and extending through the setting walls, usually at right angles to the axes of the tubes to be cleaned. Steam issuing from the nozzles dislodges the deposits. Effectively to direct the jets to clean the maximum area of heating surface, provision is made for rotating the tubes or elements as they are generally called. Such rotation is accomplished by a chain running over a sprocket wheel connected to the element by a system of gears, levers, and cams. The levers and cams serve to open the valve through which steam is supplied and to regulate the blowing arc when less than full revolution is desired. Usually a number of such units is required to clean the different parts of the boiler unit. The material of the elements is selected to withstand the temperature of the zone in which it is located.

Although considerably more economical of steam than a hand lance, mechanical steam soot blowers do cause a loss of fresh water, which may be considerable especially in large ships. To avoid such loss there are available mechanical soot blowers employing compressed air instead of steam, and many boilers are now being fitted with them.

CARE OF BOILERS OUT OF SERVICE

Boilers to be held out of service should be carefully handled and closely watched in order to minimize any tendency for corrosion of the pressure parts. A boiler to be held out of service for a period longer than 24 hr. should be laid up by either the wet or the dry method.

are in use. Single-expansion engines are used, provided the back pressure is as high as 85 to 100 lb per sq in. Such engines operate with mep of 600 to 800 lb per sq in. It is interesting to note that, under these conditions, the engines become much smaller and can be built with lighter frames and smaller bearings than equivalent engines operating with low steam pressures. The engine efficiency of high-pressure engines is as high as that of engines operating with customary low steam pressures.

A comparison of the Rankine cycle efficiencies (see p. 346) of engines using steam at a temperature of 600 F but with various steam pressures is given in Table 8 (Cramer, *Trans. A.S.M.E.*, 1915).

An incidental advantage of using high-pressure steam is that it is then available for superheating the steam passing through the intermediate receivers. Tests by Schmidt of a 150 hp quadruple-expansion engine using steam at 794 lb per sq in abs at 815 F, with 28.6 in. vacuum (*Z.V.d.I.*, June

The **wet lay-up method** is used when the boiler is to be kept available for service on short notice. The alkalinity of the boiler water should be built up to a minimum of 20 grains per gal. As the boiler is being cooled, the drain and vent valves on the superheater and the desuperheater are opened to drain any condensate. All valves on the main and auxiliary steam lines are secured. When all pressure is off the boiler, the drain valves on the superheater and desuperheater are secured, but the vent valves are left open. The boiler, superheater, desuperheater, and economizer are then slowly filled with water, adding enough compound to produce an alkalinity of 20 grains per gal. Make-up water should be deaerated if possible. The unit is filled until water issues from the vent valves which are then secured.

A hydrostatic pressure of 50 to 75 psi gage is then built up by carefully cracking the feed valve. Then the vent valves on the boiler, superheater, desuperheater, and economizer are bled to assure expelling any entrapped air. The feed valve is now secured and 25 to 50 psi gage pressure allowed to remain on the boiler. Care should be exercised so that leaking feed or steam valves do not build up higher pressure in the boiler.

The **dry lay-up method** is used when the boiler is to be kept out of service for an indefinite period. The boiler is drained completely, the manhole covers opened and enough handhole plates removed from the boiler and waterwall headers to be sure the water sides are completely dry. It may be found necessary to place coke jacks with coke or wood fires in the furnace to drive off all moisture, especially in damp climates.

Then wide shallow pans of quicklime are placed in the boiler drums, the manhole covers and handhole caps replaced, and all drain and vent valves secured.

The fire sides of the boiler, superheater, economizer, and air heater are carefully cleaned while the unit is prepared for a long lay-up. Any accumulations of soot or dirt should be removed, otherwise moisture from the air will be absorbed and cause external corrosion. All air openings should be closed and the stack cover put in place to prevent circulation of air so far as possible.

25, 1921), and with superheating in the receivers to 568, 536, and 436 F, respectively, show a total steam consumption of 5.12 lb per ihp-hr, a thermal efficiency of 31.1 percent, and an "engine efficiency" (p. 346) for the engine

WORK AND DIMENSIONS OF THE STEAM ENGINE

Simple Engines Using Saturated Steam

Ideal Hyperbolic Diagram. Figure 1 shows the typical indicator diagram *abcdef*. Nomenclature as to valve action is shown at the points *a*, *c*, *d*, and *f*. Nomenclature as to behavior of steam is designated on the intervening lines. The **idealized diagram** on which design is based is *ghjkl*, which differs from the actual diagram in showing no clearance or compression, in extending between the throttle pressure P and atmospheric or condenser pressure p, in showing sharp corners at h, j, and k, and in following the law pv = constant between h and j.

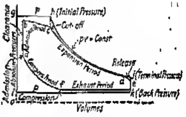

FIG. 1.—Typical Steam-engine Indicator Diagram.

Note the nomenclature adopted for pressures at h, j, and k. The volume ratio $v_j \div v_h = R$ is called the **ratio of expansion**.

The average ordinate or **mean effective pressure** of the diagram *ghjkl* is, in lb per sq in.,

$$p_m = P\frac{(1 + \log_e R)}{R} - p \tag{1}$$

in which P and p are taken in lb per sq in. abs. Table 1 gives the ratio p_m/P for zero back pressure ($p = 0$) for various values of R.

Table 1. Ratio of Mean Effective Pressure to Initial Pressure for Various Ratios of Expansion (Zero Back Pressure)

Ratio of expansion, R	Ratio of mean to initial pressure (p_m/P)	Ratio of expansion, R	Ratio of mean to initial pressure (p_m/P)	Ratio of expansion, R	Ratio of mean to initial pressure (p_m/P)	Ratio of expansion, R	Ratio of mean to initial pressure (p_m/P)

Pressures and Expansion Ratios [for Eq. (1)]. In ordinary practice, P ranges from 75 to 400; maximum value up to 1,800. Common values for simple engines are from 95 to 115. For non-condensing engines exhausting to the atmosphere at sea level, p is between 15 and 17. For condensing

of 81.7 percent, and for the individual cylinders of 91, 79.8, 78.6, and 80 percent, respectively. The heat rate was 136.6 Btu per ihp-min.

Figure 4 gives typical experimental results. The "total steam" lines illustrate the **Willans law,** that at fixed cutoff and variable initial pressure the steam consumed per hour is $a + bh$, where h = ihp and a and b are constants. Simple non-condensing engines, with initial pressures not much over 100 lb, use 24 to 28 lb of steam per ihp-hr.

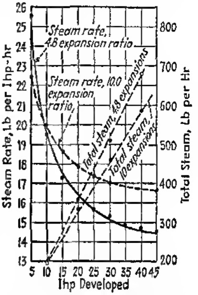

FIG. 4.—Diagram Illustrating Willans' Law of Steam Consumption.

Initial Dryness. Variation of moisture content at the throttle has no appreciable influence on economy. Carpenter and Marks (*Trans. A.S.M.E.*, 15) have shown that the **introduction of water** in proportions from 1 to 42 percent is practically **without influence on the dry steam consumption.** The water remains inert, neither helping nor hindering.

Superheat. Tables 4 to 7 show that **superheat increases efficiency,** and that ideally the increase of efficiency is nearly proportional to the amount of superheat. In practice, superheat is justified by its **influence on cylinder condensation** rather than on thermodynamic grounds. Cylinder condensation is practically eliminated when the steam is kept dry at the point of cutoff. This requires ordinarily about 150 F of superheat. The gain by superheating is progressive, probably up to that point at which the exhaust becomes superheated. **Factors favoring superheat** are slow speed, high ratios of expansion, high fuel cost, and steady load.

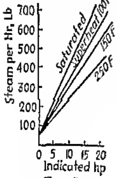

FIG. 5.

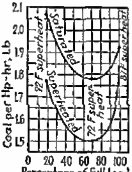

FIG. 6.

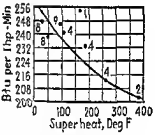

FIG. 7.—Increase in Economy of Compound Condensing Engines with Increasing Superheat.

With constant initial pressure and constant superheat, the total hourly steam consumption varies directly with the output (see Fig. 5). Experiments on H.M.S. "Brittania" show, moreover (Fig. 6) that the variation with load in over-all efficiency of plant is about the same with saturated as with superheated steam.

engines, p is between 1 and $2\frac{1}{2}$. The value 2 should be used in design. If the exhaust steam from an engine is used for heating buildings or in manufacturing processes, p may have any value from 15 upward.

The value of R is commonly around 4 in simple engines. It should increase as P increases and as p decreases, being usually between 3 and 5. It should be higher in jacketed than in unjacketed engines. The efficiency of the engine depends largely on the value chosen for R (see pp. 1034, 1035; also see under "real" and "apparent" ratios of expansion, p. 1025). High values of R will be adopted for an engine to be used where fuel is costly or the load steady. The overload capacity is similarly influenced: low values of R lead to high mep —and hence to large output from a cylinder of given size—but also to low overload capacities. In general European practice, cutoff is fixed so as to give $p_m = 18 + 0.2P$.

Upper Limits of Cutoff for Maximum Over-all Efficiency and Least Steam Consumption (Hrabak)

Throttle pressure, lb per sq in. abs	Non-condensing		Condensing		
	Simple		Simple		Compound
	Slide valve	Expansion valve	Unjacketed	Jacketed	
60	0.53–0.42	0.39–0.31	0.20–0.14	0.15–0.10	
75	0.46–0.32	0.33–0.27	0.17–0.13	0.13–0.09	0.10–0.08
90	0.40–0.28	0.28–0.23	0.15–0.125	0.11–0.08	0.09–0.07
120	0.34–0.25	0.22–0.19	0.14–0.12	0.09–0.07	0.08–0.06
150	0.29–0.20	0.19–0.17	....	....	0.07–0.05

The higher values are for operation with maximum commercial efficiency, the lower values for minimum steam consumption. The higher values given are the upper limits (latest desirable cutoff) and apply with such conditions as small engines, cheap fuel, and intermittent operation; with large engines, high-priced fuel, and continuous operation, the cutoff for maximum commercial efficiency should be made earlier.

Mean Effective Pressures Realized. The values of p_m, obtained from (1), are multiplied by a **diagram factor** f always less than 1.0, to obtain the mep likely to be realized in the actual engine. The value of f is always between 0.45 and 0.95 and usually between 0.80 and 0.95. Values given by Seaton are

Type of Engine	f
Independent cutoff, cylinder jacketed	0.90
Single valve, automatic cutoff, cylinder jacketed	0.86 to 0.88
Single valve, automatic cutoff, without jacket	0.77 to 0.81
Unjacketed throttling engines of small size and high speed	0.58 to 0.71

The following summarizes the principal influences which determine the value of f:

Influence	Effect on the Value of f
Governing by throttling as compared with cutoff regulation	Decrease 0.10 to 0.25
Jackets	Increase 0.05 to 0.15
Very early cutoff (prior to $\frac{1}{5}$ stroke)	Decrease 0.025 to 0.125
High speed (above 225 rpm)	Decrease 0.025 to 0.10
Excessive clearance (over 5 percent)	Decrease up to 0.08
Abnormally small ports and passages	Decrease 0.025 to 0.10
Interrelated valve movements (as with a single valve)	Decrease 0.025 to 0.175

The tests quoted in Table 9 show, in general, an increase in economy with increasing superheat. This is illustrated (for compound condensing engines) in Fig. 7. High superheat (to a temperature of 600 F) causes a saving of about 20 percent in simple engines, 16 percent in compounds, and 8 percent in triples (see Table 10). The simple engine with superheated steam is as good as the compound engine with saturated steam, and superheating may be regarded as **a substitute for compounding.** The compound engine with superheated steam excels the triple using saturated steam.

Back Pressure. Unnecessary back pressure causes absolute loss. Comparison of experimental results from condensing and non-condensing engines illustrates the effect of changing the back pressure from 1 or 2 to 15 or 16 lb.

Cylinder Dimensions. For a double-acting engine

$$H_i = \frac{fp_m AS}{33{,}000} = \frac{fp_m ALN}{16{,}500} = fp_m K \qquad (2)$$

$$A = \frac{33{,}000 \times H_i}{fp_m S} = \frac{16{,}500 \times H_i}{fp_m LN} \qquad (3)$$

in which H_i = indicated horsepower to be expected from the engine; A = average effective area of the piston, sq in.; L = stroke of piston, ft; N = rpm; $S = 2LN$ = piston speed, fpm; $K = ALN/16{,}500 = AS/33{,}000$, a constant for a given engine. In an ordinary double-acting engine, A is the cross-sectional area of the cylinder *minus* half the cross-sectional area of the piston rod. When a tail rod is used, the deduction is the whole cross-sectional area of the rod.

Piston Speed, Revolutions per Minute. Piston speeds range about as follows: for horizontal single-cylinder engines, 600–1,100; for vertical multi-cylinder engines, 800–1,200; for air compressors, 500–750; and for locomotives about 1,500 fpm. The higher the value of S, the greater is the power realized from an engine of given size; or the less is the weight, size, and cost of an engine of given power. With very high values of S, the question of port size and arrangement becomes especially important. Maximum values of S usually accompany maximum values of L.

The value of N is chiefly limited by the type of valve and gear. It may be fixed by the mode of application of the power. Releasing-gear engines seldom run over 100 rpm. Rotary-valve engines, without releasing gear, may work up to N = 240. Ordinary slide- and piston-valve engines may run as fast as 350 rpm; poppet-valve engines to 225 rpm for horizontal and 450 rpm for vertical engines. Large engines with releasing gear almost always run between 80 and 100 rpm. Small engines generally employ maximum values of N for the type of valve gear used. At 24 in. stroke, the speed with any type of valve gear seldom exceeds 200 rpm.

Strokes of engines running around 100 rpm vary from 1½ to 3 times the piston diameter, the ratio being less with larger-size engines. In engines running above 150 rpm, the stroke is usually about equal to the diameter. Pumping engines, which must run at low piston speeds, have long strokes, and even then the value of N is abnormally low. Long strokes favor low clearances.

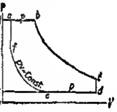

FIG. 2.—Modified Hyperbolic Diagram.

Modified Hyperbolic Diagram. In Fig. 2, the ideal diagram *abcdef* includes the influences of clearance and compression, and thus more closely approximates the indicator card than the diagram of Fig. 1. The mep is

$$p_m = \frac{P}{R}(1 + c - cR) + \frac{P}{R}(1 + c)\log_e R - p[1 + c(1 - R_c)] - pR_c c \log_e R_c \quad (4)$$

in which c = proportion of clearance = $v_a/(v_c - v_a)$, R_c = ratio of compression = v_e/v_f. When Eq. (4) is used for p_m, corresponding values of f are usually between 0.90 and 1.0.

Clearance depends upon the size of the engine, its ratio of diameter to stroke, and the type and location of valves. The **clearance volume** includes all spaces between the piston and the valve faces, when the former is at the (adjacent) end of its stroke. The linear clearance (distance from piston to cylinder head) may account for only a small part of the total clearance volume. The clearance volumes at the two ends of the cylinder are usually unequal. Designers **aim to keep clearance low.** This is more important in simple engines than in compounds, and is most important with high ratios of expan-

Such a comparison is made in **Table 11.** It shows that the condensing engine saves 26 percent over the non-condensing engine in simple four-valve types and 35 percent in releasing-gear compounds (both with saturated steam). The automatic engines profit less when running condensing, partly on account of their high compression. The simple condensing engine is more efficient than the ordinary compound non-condensing engine. With superheat, the condensing engine is more efficient than the non-condensing by 20 to 30 percent for simple types and by 23 percent for compounds.

Table 10. Comparative Results of Steam-engine Tests: Saturated vs. Superheated Steam

Altitude correspondingly affects engine efficiency and capacity, since atmospheric pressure varies about 1 lb per 2,000 ft. of elevation. In non-condensing engines, the mean effective pressure varies about ¾ lb for simples and nearly 1 lb for compounds, for this elevation. With condensing engines the variation is so slight as to be negligible.

Ratio of Expansion. Tables 2 to 7 show that ideally the efficiency varies **directly with the ratio of expansion,** and that a given amount of increase in cylinder volume pays better when the ratio is previously low than when it is high. Complete expansion (continuing until the terminal pressure is that

sion. In the low-pressure cylinders of compounds, clearances are relatively high, on account of the large ports.

Clearance Data	Percentage of Piston Displacement
Extreme range	1 to 15
Range with	
Flat slide valves at the side of the cylinder	5 to 10
Piston valves at the side of the cylinder	7 to 15
Corliss valves	2 to 8
Poppet valves, mean for 1000 hp (Lenz)	4
Flat or piston valves in the cylinder heads	2 to 7
High-speed engine } comparative values	8 to 12
Slow-speed engine } comparative values	4 to 6

"Real" and "Apparent" Ratios of Expansion. The ratio $(v_c - v_a)/(v_b - v_a)$ (Fig. 2) is the "apparent" ratio of expansion. Following the notation of Eq. (4), its value is

$$R_a = R/(1 + c - Rc) \tag{5}$$

and

$$R = (R_a c + R_a)/(R_a c + 1) \tag{6}$$

Engines are usually designed by assuming R_a and c, and then finding R from Eq. (6).

Compression has for an **extreme limit** the condition $p_f = p_a$ (Fig. 2). Where Eq. (3) is used in design, compression is regarded only as influencing the value of f. These values are low for high-speed engines partly because such engines use excessive compression. They are low for single-valve engines because such engines have high compression at light loads. Practical limits of value of p_f may be taken at $0.7(P - p) + p$ for high-speed and $0.1(P - p) + p$ for low-speed engines.

Simple Engines Using Superheated Steam

The ideal diagram of Fig. 2 represents the action of a simple engine using highly superheated steam, excepting that the expansion curve bc no longer approximates the hyperbolic. Its equation is pv^n = constant, where n has a value depending on the amount of superheat and the ratio of expansion. The value of n is about 1.10 (1.17) for 250 (400) deg F superheat. **Diagram factors** will be higher than for saturated steam though throttling, excessive speed, large clearance, restricted ports and passages, or interrelated valve movements may cause variations. **Jackets** are not used. Ratios of expansion may be 40 percent higher than with saturated steam, without reduction of diagram factor. **Piston speeds may be higher** without causing undue port friction. Corliss valves are rarely if ever used with high superheat: the poppet or piston valve may be employed.

With slight superheat, Eq. (1) is used for determining p_m, and the value of f will be governed by the considerations of p. 1023, superheating being here regarded as equivalent to jacketing.

Compound Engines

Preliminary Diagram. In Fig. 3, let the ideal diagram $habg$ correspond with $ghjkl$ of Fig. 1. The diagrams differ in that with the former the terminal pressure equals the back pressure. There is no "terminal drop" (jk, Fig. 1). In Fig. 3, the line bg represents the flow of steam, without fall of pressure, from the "high-pressure" cylinder to the **"receiver."** The latter in turn delivers

in the exhaust pipe) leads to excessive cylinder condensation, so that the ratio is standardized between 3 and 5 for simple engines and between 6 and 36 for multiple-expansion engines—multiple expansion itself serving to mitigate the influence of cylinder condensation. **Maximum economy** is obtained with relatively high ratios of expansion where jackets, reheaters, or superheat are used, and where the initial pressure is high or the engine *runs condensing*. *Low ratios may* be employed, regardless of thermal efficiency, to secure low first cost.

Most stationary engines are governed by varying the ratio of expansion, so that the change in economy with load illustrates the effect of ratios of expansion on efficiency. The curves of Fig. 8 show this. The flatter curves represent the type of engine best adapted for running economically over a wide range of loads. (For the shape of such curves with *superheated* steam, see p. 1032.) The effect of engine friction on desirable ratio of expansion is discussed on p. 1028.

Cylinder Condensation. The walls of a steam cylinder are alternately heated and cooled during each revolution. The cold walls cause condensation

steam to a "low-pressure" cylinder, the action of which is represented by the diagram *gbcef*. The two cylinders constitute a compound engine.

To avoid noticeable fluctuations of pressure along *gb*, the receiver must be large, ½ to 1½ times the size of the high-pressure cylinder; the former ratio being used for tandem engines, the latter for cross-compounds in which the cranks are usually 90 deg apart.

Maximum stresses are greater in tandem engines than in cross-compounds, and close regulation of speed is more difficult. On the other hand, the tandem costs less and occupies less space.

If this ideal diagram correctly represented the action, then a single simple cylinder of the same size as the low-pressure cylinder of the compound, working between the same extreme pressure limits and with the same ratio of expansion $R = v_c/v_a$, would give the diagram *hacef*. The simple cylinder would give the same power, then, as the compound engine.

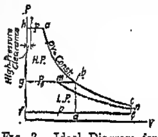

FIG. 3.—Ideal Diagram for Compound Engine.

Basis for Design. The diagram *hacef* of Fig. 3 and the output of the whole engine are determined when P, p, and $R(=v_c/v_a)$ are given. *The proportion of* work done by each cylinder depends upon the receiver pressure, P_o. The designer may proceed in any one of five ways:

1. The receiver pressure may be assumed.

2. The temperature ranges may be made the same in both cylinders. This is probably the best basis with high initial pressures. Then $T_b = (T_a + T_c)/2$, where T_b, T_a, and T_c are (for saturated steam) the temperatures corresponding, respectively, with the pressures P_o, P, and p, from which T_b and P_o may be found.

3. The cylinders may develop the same power, in which case

$$\log_e P_o = \tfrac{1}{2}\left(\log_e R + \frac{Rp}{P} - 1\right) - \log_e \frac{R}{P} \qquad (7)$$

4. The total maximum piston pressures may be equalized, when

$$P_o = P^2/(P + P_oR - pR) \qquad (8)$$

5. The ratio of volumes of the cylinders may be assumed, as $C = v_c/v_b$;

$$P_o = CP/R \qquad (9)$$

Mean Effective Pressures. Having determined P_o by any one of these five methods, and having noted the corresponding value of $C = RP_o/P$, the **approximate mean effective pressures** are, based on Fig. 3,

$$\text{high-pressure, } p_{mh} = [P/R_h] \log_e R_h = [PC/R] \log_e R_h \qquad (10)$$

$$\text{low-pressure, } p_{ml} = [(P_o/R_l)(1 + \log_e R_l)] - p = [(P/R)(1 + \log_e C)] - p \qquad (11)$$

where R_h = ratio of expansion in high-pressure cylinder $= v_b/v_a$;
R_l = ratio of expansion in low-pressure cylinder $= v_c/v_b = C$;
other symbols being as in Eq. (1).

The value of C is usually 2.5 to 3.5 in non-condensing and 4 to 6 in condensing engines. It should vary directly with R. If it is made too great, the engine will, though probably economical of steam, be costly to build and deficient in overload capacity.

At a fixed ratio of expansion R, the output of the engine is independent of the size of the high-pressure cylinder. Exceptionally high efficiencies have been obtained with value of C around 6 or 7 (see p. 1037). When no account of having reached the limit of size (about 100 in. diam), more than one low-

of steam during admission and possibly during the early part of expansion, the heat transfer being at the rate of 20 to 25 Btu per sq ft per deg of temperature difference per minute. This is followed by an evaporation of the steam during late expansion or exhaust.

See Callendar and Nicolson, *Proc. Inst. C.E.*, 131, pp. 147–268; Duchesne, *Rêvue de Mécanique*, 19, pp. 1–40; Mellanby, *Proc. Inst. Engrs. and Shipbuilders of Scotland*, 1911; Barraclough and Marks, *Min. Proc. Inst. C.E.*, 120, ii.

Since most of the condensation occurs during admission, the dryness at cutoff is a measure of economy. This may be ascertained by comparison of the indicator diagram with the experimentally determined steam consumption. The dryness at cutoff and the economy are directly influenced by the size of the engine, its speed and, chiefly, by its ratio of expansion. Figure 9 shows a typical relation between cutoff dryness and ratio of expansion. Up to a certain point, the thermodynamic gain associated with high expansive ratios more than offsets initial condensation.

Jackets. *The steam jacket, by raising the temperature of the walls,* reduces heat transfer. The jacket should be supplied with steam on its way from the throttle to the cylinder. The circulation must be free, and air pockets must be avoided. Superheat is a better device than jacketing if high

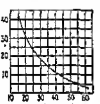

FIG. 9.—Variation of Initial Condensation with the Expansion Ratio.

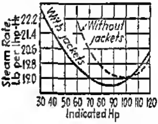

FIG. 10.—Saving Due to Jacketing.

thermal efficiency is sought. Jackets should not be needed when superheat is used.

In nearly all tests reported, the jacket shows some net gain; but unfavorable results may not be published. From 0 to 30 percent (usually 0 to 10 percent) saving in total steam consumption may be effected, the jacket meanwhile consuming 7 to 16 percent (usually 7 to 10 percent) of the total steam. *Average in 10 compounds, 10.2 percent; in 5 triples, 5.8 percent. The lower* percentages occur when superheated steam is used in the cylinders. See p. 1037 as to the omission of low-pressure jackets when reheaters are used. Figure 10 shows results of a test by Carpenter, the saving by jacketing varying directly with the ratio of expansion and becoming negative at very low ratios.

Multiple expansion *permits a high ratio of expansion without excessive* cylinder condensation, and therefore increases efficiency. Roughly, the compound uses 20 to 30 percent less steam than the simple engine. The triple may use 10 to 15 percent less than the compound. These savings (particularly those of the compound over the simple engine) are due partly to the higher initial pressure and lower leakage and clearance losses usually associated with multiple expansion.

The use of superheated steam and the uniflow engine have superseded compounding but it is sometimes resorted to as a means to reduce piston loads.

Triple-expansion engines for marine applications are economical and fairly well balanced. Average cylinder ratios are 1:2.7:8. The size of the high-

trades and industries. The most common of these are the A.P.I. and Baumé. The A.P.I. (American Petroleum Institute) scale is approved by the American Petroleum Institute, the A.S.T.M., the U. S. Bureau of Mines, and the National Bureau of Standards and is recommended for exclusive use in the United States petroleum industry, superseding the Baumé scale for liquids lighter than water. The relation between A.P.I. degrees and specific gravity is expressed by the following equation:

$$\text{Degrees A.P.I.} = \frac{141.5}{\text{sp gr } 60°/60°\text{F}} - 131.5$$

For the salinometer (salometer), see p. 2167. The specific gravities corresponding to the indications of the Baumé hydrometer are given in the following tables.

pressure cylinder determines the overload capacity. Engines with small high-pressure cylinders are very limited in this respect. Clearance volume of high-pressure cylinders has little influence on economy. The reverse is true of low-pressure clearance.

Table 12. Average Steam Rates (Lb per Ihp-hr) with Saturated Steam
(From Stanwood, Barrus, *Proc. Inst. C.E.*, 93, Willans, Clark, *Trans. A.S.M.E.*, 21, etc. Compare with Table 9)

Type of engine	Non-condensing			Condensing		
	Single valve	Double valve	Four valve	Single valve	Double valve	Four valve
Simple	33	30	28	27	42	21
Compound	24	23	22	20	16	14
Triple	..	..	18½	..	..	12

High-ratio Compounds. The best triples have only slightly surpassed the best compounds. With high cylinder ratio, 6 or 7 to 1 (p. 1026), about 30 expansions, and 150 to 200 lb initial pressure, jacketed compound engines have repeatedly consumed about 12 lb of steam of ihp-hr. (*Trans. A.S.M.E.*, **13**, p. 647; **19**, pp. 155, 167, 189; *Power*, July, 1904, p. 424; Barrus, "Engine Tests," No. 47).

Reheaters. The reheater does for the low-pressure cylinders of a multiple-expansion engine just what superheat does for a single cylinder (*Trans. A.S.M.E.*, **25**, 482–492). Adequate reheat involves superheating the steam in the receivers by from 30 to 100 F. With the latter amount, Marks has shown (*op. cit.*) that the efficiency of the (compound) engine may be increased 6 to 8 percent. Good reheating makes low-pressure jackets unnecessary. With moderately superheated steam in both cylinders, the steam consumption per ihp-hr is about constant for the range from ½ load to 1¼ load.

Speed and Size. Cylinder condensation is reduced by high rotative speed, but the efficiency is not usually increased thereby. Along with high speed comes a limitation of choice of valve gear and (usually) imperfect distribution of steam. Slight variations in speed are practically without effect on the economy.

Small engines are usually wasteful. In sizes from 2 to 5 hp, non-condensing, a compound engine used 42 lb of steam per ihp-hr.; simple engines, 78 to 89 lb (*Engineering*, June 27, 1890). Thermal efficiency is not improved with large size; some of the best records have been made by units of not much over 100 hp capacity.

Clearance and Compression. Clearance is a necessary evil and should be kept as small as possible. The heat losses to the walls increase as the clearance increases. This is one of the reasons why small engines (with relatively large clearances) are wasteful and compound engines (which usually have small clearances) are economical. Klemperer gives (*Z. Ver. deut. Ing.*, **1**, 1905, p. 797), for a 7 by 18 in. Corliss engine, non-condensing, with 4½ percent clearance, 25.6 lb steam per ihp-hr; with 15.2 percent, 28.5 lb. A moderate amount of compression (varying with the speed) is justified on mechanical grounds.

Friction. The laws of friction indicate that the power lost in friction should increase somewhat with the load in either a variable-cutoff or a variable-speed engine. Conditions of workmanship and lubrication make it difficult to confirm this by actual tests of engines (see p. 1028), and the friction loss is usually regarded as constant for all loads—an assumption which

moved *to the left* a *relative* distance equal to its lap, *l*. The *absolute* movement of the auxiliary necessary to produce this relative displacement depends on the amount of movement of the main valve meanwhile taking place. The lap (and point of cutoff) may be varied by hand, by turning the valve rod; or the latter may be under the control of a governor which shifts the eccentric so as to change the angle of advance of the auxiliary. The double-piston valve gear made by the Ingersoll-Rand Co. has a separate cut-off valve.

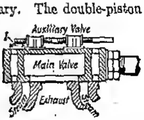

Fig. 6.—Meyer Cutoff Valve.

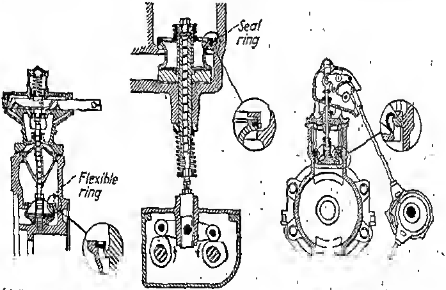
The **Rider valve**, like the Meyer, incorporates an auxiliary cutoff member, but the lap is changed either by rotating or transversely moving the auxiliary. In the former case, the expansion valve is of the piston type, working in a hole bored lengthwise in the main valve. From this passage, the steam ports are cut obliquely, as are also the lap ends of the auxiliary. When transverse displacement is practiced, the auxiliary is flat and of trapezoidal outline.

Poppet valves have vertical spindles, and usually lift to open. There are commonly four independent valves per cylinder. The exhaust valves are always below the steam valves. The seats are usually double and are nearly balanced, a sufficient unbalanced pressure being provided to insure tightness when closed. It is usually attempted to equalize the two steam-passage areas provided. Figure 7 shows some forms.



(a) Flexible poppet valve with seats machined in the cylinder head (b) Resilient poppet valve with double cam shaft gear (c) Rigid poppet valve in cage

Fig. 7.—Poppet Valves and Gears.

In some types of engine, the valves are operated direct from eccentrics, the minimum number of the latter being two, one each for steam and exhaust valves. More commonly, a pair of miter gears connects the engine shaft with a shaft, from which the valves are driven by eccentrics and cams.

Revolving cams are used to large extent with multicylinder uniflow engines; they are suitable for high rotative speeds. Two forms of such gears have come into use. One form employs a single cam, which is made helical on the closing side and is shifted in direction of its axis to vary the cutoff, and the other type (Fig. 7*b*) has two cams on

underlies the determination of mechanical efficiency by taking a "no-load" or "friction" indicator diagram.

The mechanical efficiency in important engines is usually between 0.9 and 0.96 at full load. The highest record seems to be nearly 0.98. Values below 0.85 are exceptional. The steam rate and thermal efficiency may be referred to brake output by introducing the mechanical efficiency as a factor.

The greater part of engine friction occurs at main bearings. Friction of piston rings and stuffing boxes comes next in importance, and the latter item may be considerably varied in operation. Unbalanced slide valves add greatly to friction losses.

Rotary engines, since the advent of the turbine, have ceased to be even desirable. Of the thousands which have been invented and forgotten, practically all manifested excessive leakage due to the substitution of line contact of wearing parts for the surface contact of an ordinary piston. Even those which are tight at first soon develop leakage.

Uniflow Engines

The typical uniflow engine (Fig. 11) has central exhaust ports which are uncovered by the piston near the end of its stroke. To accomplish this,

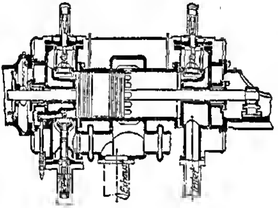


Fig. 11.—Uniflow Engine.

the piston is made of unusual length. Steam enters the cylinder usually through double-beat poppet valves (with flexible upper seat to ensure tightness under varying temperature) or through high-lift single-beat poppet valves, and, after expansion, exhausts through the central ports. The cooling of the cylinder walls and the clearance surfaces by the flow of exhaust steam past them, which is characteristic of the normal alternating- or counter-flow engine, is thereby avoided and the resulting cylinder condensation is greatly reduced. By steam-jacketing the cylinder head, the cylinder condensation loss is still further diminished and this effect is increased by compression up to the initial steam pressure. The exhaust ports close usually at 8 to 10 percent of the return stroke. The clearance in condensing engine is usually 2 to 3 percent or even less; the resulting small clearance surface is a further factor in reducing cylinder condensation.

The permissible expansion ratio in the normal steam engine is limited by the cylinder condensation loss. This limitation does not exist in the uniflow engine which can expand steam from 200 lb per sq in. or higher to a vacuum of 28 in. with an economy which is equal to or greater than that of multicylinder engines of normal type. By expansion in a single cylinder, the

parallel shafts. One cam is retarded and advanced with respect to the other, and the combined motion of the two cams is transmitted to the valve. Cam gears of this type are suitable for any desired cutoff range and for early cutoff give valve lifts that are considerably larger than can be obtained with eccentric gears.

Valve Gears

Rotary Gear. The Corliss valve is skeleton cylindrical, located transversely. It rocks back and forth through a small arc. Separate steam and exhaust valves are provided at each end of the cylinder. Some forms are shown in Fig. 8. The **typical Corliss valve gear** is shown in Fig. 9. If releasing cutoff is to be effective at cutoff later than half-stroke, separate eccentrics are used for steam and exhaust valves. The **diameters of such cylindrical valves** range from 4 to 5 times the maximum port opening. The **length of ports** is about equal to the bore of the cylinder.

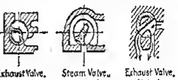

FIG. 8.—Corliss Valves.

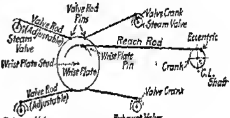

FIG. 9.—Typical Corliss Valve Gear.

Valves are usually located at the ends of the cylinder, the steam valve above and the exhaust valve below. The Corliss gear has small travel and slight friction. It gives particularly small clearances, though designs differ somewhat in this respect. Live steam and exhaust steam never pass through the same port. The valve is not suitable for use with high steam temperatures.

A fundamental feature of a Corliss engine is the **releasing gear.** In Fig. 10, the crank A is loosely mounted on the valve stem, and the grab hook H is loose on a pin fixed in A. The spring S presses the grab hook against the knock-off cam C, the position of which is controlled by the governor. C rocks freely on the valve stem, but the lever B is keyed to the stem.

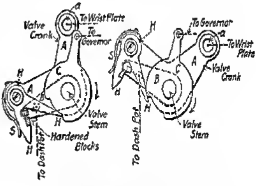

FIG. 10.—Releasing Gear of Corliss Engine.

In the left half of Fig. 10, the valve is about to rotate clockwise. This rotation is produced by the train A, H, B. Simultaneously, the rod running from B to the dashpot rises. As the motion proceeds, the upper of the hardened-steel blocks slides to the right, disengaging from the lower block—as indicated in the right half of Fig. 10. A vacuum dashpot then pulls down on B by means of the vertical rod, closing the valve by a quick counterclockwise rotation. The point of disengagement is determined by the position of the cam C.

transfer losses (pressure drops) between cylinders are avoided and the engine is much simplified and cheapened. Leakage losses are less and the back pressure is diminished because the exhaust ports have an area several times greater than the usual passage past the exhaust valve.

For **non-condensing operation,** some modification of the uniflow engine is necessary to avoid excessively high compression pressures. Generally, there is some departure from the strict uniflow principle. This is either in the form of an auxiliary exhaust valve in the cylinder head or additional clearance volume (pockets connected with the cylinder through an automatically or hand-operated relief valve). Condensing engines also have to be fitted with one or other of these devices which will come into action automatically in case the vacuum fails. The clearance for 100 (200) lb initial pressure is about 20 (12) percent with non-condensing operation. Auxiliary exhaust valves delay the beginning of compression and give a higher mep for a given ratio of

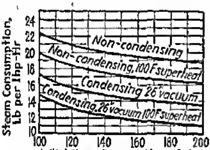

FIG. 12.—Steam Consumption of 400 Hp Uniflow Engine.

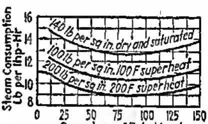

FIG. 13.—Steam Consumption of Uniflow Engine with 27½ in. Vacuum.

expansion than is obtainable with increased clearance volume but probably with some small decrease in economy.

The **steam rates** of uniflow engines are low as compared with other engines. The curves of Fig. 12 for a 400 hp engine may be taken as typical of the results obtained by the best American builders of these engines and should be compared with the performances of the usual type engine as given in Tables 9 and 12. The best results may be 5 to 10 percent better than those shown. The economy does not improve much for larger sizes; for 50 hp, the economy is about 10 percent less than for 400 hp. A notable characteristic is the **small variation in economy with load;** this is shown in Fig. 13. The normal early cutoff permits a considerable overload, usually to 175 percent of rating. Tests with high superheat have yielded the following results in condensing engines:

Observer	Engine	Steam	Lb steam per ihp-hr
Stumpf	24½ by 39 in.	140 lb, 376 F	12.25
Stumpf		120 lb, 490 F	10.85
Stumpf		162 lb, 518 F	9.9
Burmeister and Wain	115 to 220 hp	140 lb; 667 F	9.06 to 9.68
Lentz	100 hp	235 lb, 923 F	6.52
Lentz	100 hp	461 lb, 1018 F	5.67

Mechanical efficiencies are high, ranging from 92 to 96 percent. These engines are now being built in sizes up to 10,000 ihp per cylinder peak load capacity, or 20,000 ihp for twin engines.

Ordinary releasing gears do not work well at speeds above 100 rpm. Corliss valves without disengagement, operated by one fixed exhaust eccentric and a steam eccentric under control of the shaft governor, are a feature of the so-called "four-valve" engine.

Reversing Gears

An engine may be arranged to run in either direction at will, by (1) interchanging steam and exhaust ports; (2) using two alternative eccentrics, with optional engaging grabs; (3) shifting the eccentric back by an angle exceeding 180 deg + the angle of advance; (4) using a reversing gear.

The **reversing gear** is **virtually equivalent to a shifting eccentric**, but with greater flexibility of control, since it changes both position and travel of the valve. In addition, the linkage may correct inequality of distribution due to angularity of connecting rod. It does not actually move the eccentric, but its effect is the same as that due to a movement of the extremity of the valve circle from c along some such path as cp, Fig. 5. This path being determined, the steam distribution may be examined as in Fig. 5. A reversing gear may be used to give gradual variation of cutoff.

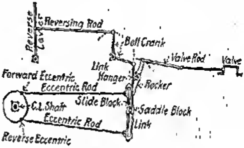

Fig. 11.—Stephenson Link Reversing Gear.

In the **Stephenson link** (Fig. 11), the eccentrics are treated as equivalent to two short cranks, driving the eccentric rods, which are hinged to the link. The radius of curvature of the link is equal to the length of eccentric rods. The valve is moved by the link by means of the slide block, rocker, and valve rod. The link may be raised or lowered by the reversing lever, reversing rod, bell crank, and link hanger. When the link is in its lowest position, the valve derives its motion from the upper eccentric rod entirely, the lower rod serving merely to rock the link about the slide-block pin as a fulcrum. In its uppermost position, the link and valve are effectively moved by the lower eccentric rod alone. At these positions, the valve travel is a maximum. A mid-height on the link, the travel is a minimum, and the motion is determined by both eccentric rods. The movement of the link from one extreme position to the other thus gradually changes the angle of advance and the travel, and both may be fixed temporarily at any desired value between the extreme limits. To minimize slip at the slide-block bearing, the slide block should be immediately under the saddle block at the usual running adjustment.

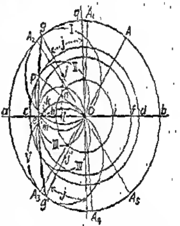

Fig. 12.—Diagram of Stephenson Link Motion.

Figure 11 shows a link motion with "open" rods. Sometimes the rods are "crossed"; i.e., when the crank is at left dead center and the eccentrics are between it and the link, the projections of the rods cross each other. (In either construction, the rods appear

Binary Vapor Engines

Steam is an unsatisfactory working substance because of (1) the limitations which it imposes on the operating temperature range of the engine, (2) the difficulty of maintaining the high vacuum corresponding to low exhaust temperatures, and (3) the excessive volume of a reciprocating engine required at such low pressures. By using a vapor with a higher boiling temperature, the maximum temperature of the cycle can be increased without corresponding increase of the vapor pressure.

A **steam-sulphur dioxide system** has been used in reciprocating engines. This extends the temperature range at the lower limit and avoids the necessity of maintaining a high steam vacuum. As worked out by Josso, the steam expands to about 3 lb abs (142 F) and on condensation generates sulphur dioxide vapor at about 160 lb per sq in. This vapor expands down to about 50 lb per sq in. (70 F) before it is condensed. To reduce steam to the same temperature would require the maintenance of a vacuum of 29.3 in., which is impracticable in a reciprocating engine. The sulphur dioxide engine is of small bulk as a result of its high pressure. Added as a third cylinder to a compound steam engine, it has increased the power output and thermal efficiency about 50 percent. This system has not proved commercially successful.

Mercury vapor and steam make a binary system which can be used for extending the upper temperature limit and is so used in certain turbines but is not practicable for a reciprocating engine.

Regenerative Cycle: Quadruple Engines. By using the receivers as successive feed-water heaters, remarkably high thermal efficiencies have been reached in certain quadruple engines. The cycle of such engines is described in *Trans. A.S.M.E.*, **21**, p. 181; **28**, No. 2, p. 221. The Wildwood pumping engine, 712 hp, 200 lb pressure, partly jacketed, used 186 Btu per ihp-min. A 1,000 hp Nordberg compressor with 257 lb steam pressure used 169 Btu. The steam rate does not measure the efficiency in this type of cycle. These results were reached with saturated steam. A similar practice is common with steam turbines (see p. 1258).

Engine efficiency is the term used for the ratio of the heat input per ihp in the ideal engine using the Rankine cycle (p. 346) to the heat input per ihp of the actual engine. It was formerly called the **efficiency ratio** (sometimes the Rankine efficiency). Its average values are about as follows, expressed in percent. Simple engines, single-valve, non-condensing 61, condensing 41. Simple engine, four-valve, non-condensing 70, condensing, 51. Compound, non-condensing 72, condensing 69. Triple, condensing 73. Superheat increases these values. For the Schmidt high-pressure engine (see p. 1030), it is 81.7. Its value is higher for the h-p cylinder of a compound than for the l-p cylinder.

Present Status. The steam engine is used extensively in sizes up to about 1,000 kw for producing power and for driving compressors; it is also used for locomotives and to a diminishing degree in the marine field. Stationary engines when horizontal are usually single-cylinder. Vertical engines of 3, 4, and 5 cylinders are extensively used and operate at higher rotative speeds with the advantage of cheaper generators and small floor space; they are generally of the uniflow type.

Compound engines are built for two-stage air or gas compressors. Triple-expansion engines are built for ships. Aggregate turbine installations passed those of steam engines in 1924.

crossed at certain crank positions.) With crossed rods, the supply of steam may be cut off at mid-position of the link. With open rods, there is positive lead at all positions.

Figure 12, following the construction of Fig. 6, shows the successive equivalent valve circles I, II, III, IV, V, as the link is shifted from "forward" to "reverse" position. The "equivalent eccentric path" is $gpeg'$. In progressing from "full" to "mid" gear, travel and port opening decrease and lead increases. The crank positions at cutoff are A, A_1, and A_2. Proceeding from mid gear to full reverse, cutoff occurs successively at A_2, A_4, A_5 *(rotation now counterclockwise)*.

With constant lead, the path $gpeg'$ would be a straight vertical line. In the Stephenson link, it is a parabola, closely coinciding with a circular arc drawn through g, g', and e, such that $oe = og\,(\cos goa \pm m \sin goa)$, where m is the ratio of link length to rod length. (The + sign is for open rods, the − sign for crossed rods.) Lead at full gear, with open rods, is usually $\frac{1}{16}$ to $\frac{3}{16}$ in.

Radial gears employ a guiding arm in place of a link. In most of them, the lead is constant, and the *path $gpeg'$ (Fig. 12) is a straight vertical line.*

The **Hackworth gear** (Fig. 13) has the eccentric rod EQ terminating at Q in a slide block. This block moves in a straight slot, the position of which is adjustable. The pin P moves in an ellipse, the proportions of which are determined by the position of the slide-block slot. The gear gives good steam distribution with sharp cutoff, and is compact.

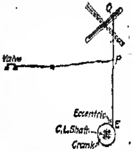

FIG. 13.—Hackworth Valve Gear.

In the **Joy gear** (Fig. 14), the valve is moved partly from the connecting rod by the linkage a, b, c, but the movement is modified by the position at which the movable fulcrum d of the radius bar e is set. There is no eccentric. A slotted guide (as in the Hackworth gear) may replace e. The Joy gear gives quick cutoff, well-balanced and moderate compression.

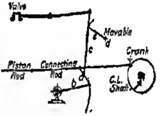

FIG. 14.—Joy Valve Gear.

The **Walschaerts gear** (Fig. 15) also combines two methods of driving: one from the crosshead, through e, f, g, h, and one from the eccentric (90 deg out of phase with the crank) through the eccentric rod, link, and radius rod attached at g. The slide block by which the radius rod is moved from the link is vertically adjustable. When the slide block is in line with the link fulcrum, the valve is moved by the crosshead alone. The link radius is equal to the length of the radius rod. If, when the piston is on dead center, the center of the link arc coincides with g, the lead will be constant. Without the crosshead linkage, there would be no lap or lead or expansion. The effect of this linkage is to increase the displacements of the valve. Minimum travel is determined by analyzing this linkage as it operates when the slide block is under the link fulcrum. Maximum travel occurs when the slide block is at one of the ends of the link. Unless the prescribed proportions are followed, the lead will vary about as it does in the Stephenson gear. The Walschaerts gear as applied almost universally to locomotives uses a supplementary

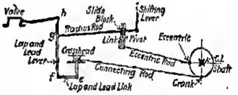

FIG. 15.—Walschaerts Valve Gear.

The types most built (on the basis of aggregate horsepower) are the four-valve and the uniflow: the former, usually, for non-condensing operation. Single-valve throttling engines of small size are built only for unimportant plants.

(*E*) Engine efficiency based on ihp, 79.4 percent (steam temperature 581 F).

Relative Efficiency of Steam Engines and Turbines. The efficiency of the steam engine, compared with the turbine, depends chiefly on the size of unit and operating pressure. Leakage of steam around the blades is high in small turbines, and this loss is greater at higher pressures. On the other hand, higher initial temperatures are used on turbines, in the United States, and the turbine can utilize higher vacuum. In general, large condensing turbines require less steam than large condensing engines, but small non-condensing engines use less steam than turbines of the same size and pressure range. Table 14 gives water rates for engines and turbines. The figures given are the average for a number of installations and are based on steam temperatures of 450 F for small engines, and 550 F for the larger ones; the

outside crank in place of an eccentric. The mechanism is all outside, and occupies little width. Cutoff and lead may be equalized for the two ends.

Engine Parts

Bearings (see p. 863). Modern engines are usually equipped with pressure lubrication. Bearing pressures for high-grade side-crank engines average as follows: Crankpin, 1,300; crosshead pin, 1,700; main bearing, 300; outboard bearing, 150 lb per sq in.

Crank and crosshead pins are made large in diameter and short in length to avoid deflection. Connecting rod ends are shaped for stiffness. Wedge adjustment of bearings is usually omitted.

Main bearings of the quarter box type are still used with side crank frames. The tendency is toward bearings in halves, with the split at 45 deg.

Frames are usually made of cast iron. Sometimes the metal is held in compression by means of through tie rods. Welded frames are also used, with cast-iron crosshead guides bolted in place. With pressure lubrication, attention must be paid to oil tightness and quick collection and removal of oil. Proper ventilation of the crankcase is essential to retain oil mist.

Crosshead guides of horizontal engines are bored and the end face machined at the same setting, to ensure alignment. With high-temperature steam, the cylinder must be insulated from the frame either by restricting the contact area or by interposing distance pieces; alignment between cylinder and guide under these conditions must be obtained by other means. Flat crosshead guides with slipper-type crossheads are preferable as this type of crosshead can operate with smaller running clearance and is therefore better suited for high-speed engines.

Cylinders (see p. 845) are usually made of a semisteel mixture occasionally with the addition of nickel. Highly superheated steam requires careful design to eliminate temperature stresses. Poppet-valve cylinders for such service usually have separate steam and exhaust connection for every valve. Piston-valve cylinders, with inside admission valves, have a semiflexible valve housing with the exhaust passages attached separately.

Valves. Unbalanced slide valves are found only on small engines and direct-acting pumps. Piston valves are universally used on locomotives, either single or double ported. Surviving also is a form of double piston valve, the equivalent of the Meyer valve. Piston valves, in most cases, operate in separate cast-iron bushings and have snap rings for tightness.

Corliss valves are found in a variety of forms. Steam valves are usually double ported (see Fig. 8). They are used with superheated steam up to about 100 F superheat, in which case special oil feeds for the rubbing surfaces of the valve are provided. Non-releasing Corliss gears employ a wrist-plate motion, to reduce the valve travel during periods of unbalance. Such gears require powerful governors of the flywheel or oil-relay type.

Poppet valves are in general use with high-grade engines. They are usually made double-ported, although single-beat valves are used as exhaust valves with uniflow engines. Double-beat poppet valves have two seats in two planes. The distance of the two seats should be held as small as possible unless a resilient type of valve (Fig. 7) can be used. They can be made nearly balanced, at the expense of tightness.

Rigid cast-iron or cast-steel valves seat in cages made of the same material as the valve. If seats are machined either in the cylinder or the cylinder head, resilient valves are used to compensate for uneven expansion. Resiliency is accomplished either by flexibility of the valve itself, in which case a certain degree of unbalance must be provided, or by a built-up construction which requires an additional seal between the valve parts. Steam tightness of poppet valves is as much a matter of design as of workmanship. Valve stems of poppet valves are sealed in long cast-iron bushings with annular grooves to obtain a labyrinth effect; the slight leakage is piped off. Absence of friction and wear, except in cases of misalignment, are advantages of this type of seal.

Customary values of steam velocity past valves are: Steam valves, 200 to 300; exhaust valves, 120 to 180 fps. Exhaust port areas of uniflow engines, with the engine piston acting as a piston valve, are considerably larger than can be obtained with separate exhaust valves. Such engines therefore can utilize lower condenser pressures than engines of the counterflow type.

corresponding temperatures for turbines are from 550 to 725 F. The water rates for a condensing machine are based on 27 in. vacuum for engines and 28½ in. vacuum for turbines.

Table 14. Water Rates for Steam Engines and Turbines
(Lb steam per bhp)

Bhp		100		1,000		5,000	
Throttle pressure, lb gage	Back pressure	Engine	Turbine	Engine	Turbine	Engine	Turbine
250	Condensing	16	15	13	10	12.5	9.5
250	10 lb gage	20	27.5	17.5	21	17	18
400	Condensing	12.5	12	12	9.5	11.5	8.5
400	10 lb gage	16.5	22.5	15.5	17	15	15

While the turbine has largely replaced the reciprocating engine as a prime mover, the latter is still used to advantage:

1. Where extreme flexibility of speed control is required, and particularly where reversal of the direction of rotation is necessary, as in locomotives and rolling mill engines.

2. On small non-condensing machines operating at high initial steam pressures, and on machines operating over wide ranges of load and where low steam consumption is essential.

3. For direct drive of reciprocating machinery, such as compressors and pumps.

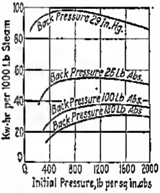

FIG. 14.—Effect of Initial Pressure on Power Obtainable from Steam at 725 F, for Various Back Pressures.

High Back-pressure Engines. For units of small capacity, the reciprocating engine ordinarily requires less steam per unit of output than a turbine. This advantage is marked in the case of high-pressure non-condensing machines and particularly so when operating against high back-pressure.

Figure 14 shows the kwhr obtainable (in engines of from 600 to 3,500 kw capacity) from 1,000 lb of steam per hr at various initial pressures, at 725 F, and with various back pressures (see Ryan, "Higher Steam Pressures in Industrial Plants," *Trans. A.S.M.E.*, 47, pp. 779–797). A comparison with the performance of a steam turbine—1,500 kw capacity—with initial pressure 400 lb abs, back pressure 180 lb abs, steam temperatures 650 F for the engine, 725 F for the turbine, is as follows:

Approximate Water Rates with High Back Pressure of Steam Engine and Steam Turbine

Load, kw	500	1000	1500
Engine water rate, lb per kwhr	73	56	53
Turbine water rate, lb per kwhr	75	69	68

The cost of an engine generator is greater than that of a turbine generator, it occupies more space, and the exhaust is contaminated with oil. Furthermore, the external heat losses are greater, so that the over-all thermal efficiency

Governors (see p. 859). Close regulation requires heavy flywheels, since the inherent friction of a governor necessitates a change of speed before the governor can come into action. A heavy wheel reduces angular acceleration to a point where overregulating and hunting is eliminated.

For a-c generator drives, a regulation of 4 to 6 percent is needed to maintain load distribution, if two or more engines run in parallel. Closer regulation may make load distribution indefinite.

Governors of engines driving a-c generators have attachments to vary the speed plus or minus 5 percent for synchronizing purposes. A small electric motor built into the wheel is used with flywheel governors, changing the tension either of the main governor spring or of an auxiliary spring. Lay-shaft governors, built with two weights for balance, employ a push rod in the hollow bored lay shaft to actuate the speed-changing device.

Variable-speed engines are usually equipped with variable-speed governors which maintain practically uniform regulation over the speed range. In some cases, indirect governing is employed, particularly with speed ratios of 1 to 4 or more.

The natural frequency of oscillation of the governor must differ sufficiently from the frequency of engine impulses to avoid conditions of resonance.

Piston rings (see p. 847) are made of semisteel and are narrow, concentric, and split. The joint is secured by dowels or spring-loaded plugs. Piston-ring joints should not be permitted to travel across ports in the cylinder wall in uniflow engines. Rings have small wall pressure and do not travel into the counterbore of the cylinder.

With high-pressure and high-temperature steam, piston-ring wear is sometimes a problem. Pure steam and the correct relative hardness of ring and cylinder surfaces are essential.

Piston and Piston Rods (see p. 846). Horizontal engines of the slow-speed type are built with self-supported pistons. Bull-ring construction offers a means to compensate for wear of cylinder and piston. Engines operated with high-pressure and high-temperatures steam should have floating pistons (tail rod) with piston rings alone making contact with the cylinder wall. Deflection of the piston rod, on large engines, is compensated for by cambering the rod.

when the exhaust steam is utilized as process steam is less than that of a turbine.

The **highest steam pressure** used for generation of power in the United States is 1840 lb at 820 F. Two boilers designed for that pressure are installed at the Lockland, Ohio, plant of the Philip Carey Mfg. Co. Power is generated in two 6,060 hp, five-cylinder, three-crank triple-expansion vertical engines, direct connected to 3,700 kw a-c generators. Steam is supplied to the throttle at 1,400 lb gage pressure and 800 F total temperature. Steam passes through two single-acting high-pressure cylinders, two single-acting intermediate-pressure cylinders, and one double-acting low-pressure cylinder, exhausting at 60 lb gage. Plant designed by W. E. S. Dyer.

Sulzer Brothers build 850 kw single-cylinder engines with steam pressures of 1,350 to 1,500 lb gage, temperatures 700 to 800 F, and back pressures 85 to 225 lb gage (*Z. Ver. deut. Ing.*, **81**, 1938). The cylinder dimensions are 10 × 23.5 in., the speed 250 rpm, and the mep at full rate 670 lb. The maximum piston load is 85,000 lb, which is less than the load on standard engines with 150 lb gage pressure operating at 150 rpm.

Steam Engines for Compressor and Pump Drives. The reciprocating engine is specially adapted for driving compressors and pumps, because of the higher efficiency of the driven unit, as compared with centrifugal machinery, as well as of the lower steam consumption of the prime mover.

The following tabulation compares the duty obtained from a 15 million gal cross-compound pumping engine with that of a turbine-driven centrifugal pump of the same capacity. Both pumps were built by the same maker and installed at the same plant. The advantage of the reciprocating unit is particularly marked at partial loads.

Duty in Million Ft-lb per Million Btu

Capacity, million gal daily	6	9	12	15
Horizontal cross-compound engine	141	143	146	147
Turbocentrifugal pump	...	...	114	124

There are in use in this country, in chemical plants, steam engines driving compressors and pumps, which operate with pressures of about 400 lb gage and with steam temperatures of 600 to 650 F. Some of these engines have back pressures as high as 225 lb, necessitating large clearance volumes to control compression.

VALVES AND VALVE GEARING

Valves and Valve Diagrams

Action of the Valve. In Fig. 1, the **slide valve**, shown in central position, admits steam from the steam chest A through the steam ports a, a', and allows exhaust steam to flow from the cylinder through a, a', to the exhaust port b. **Steam laps** (or "laps") are represented by de and nm; **exhaust laps** are represented by fg and jk. (Either or both may be negative. A negative exhaust lap must be less than the adjoining steam lap.) **Admission** occurs through a when the valve is displaced to the right by the lap de, or through a' when it is displaced to the left by the lap mn. **Maximum port opening**, usually less than the **port width** ef which is designed for the passage of exhaust steam, is attained (on the left side of the piston) when the valve is

RECIPROCATING MARINE STEAM ENGINES

BY

WAYNE T. DIMM

REFERENCES: Bragg, "The Design of Marine Engines and Auxiliaries," Van Nostrand. Seaton, "Manual of Marine Engineering," Van Nostrand. Bauer and Robertson, "Marine Engines and Boilers," Henley. Dyson, "Practical Marine Engineering," International Marine Engineering Press. Furman, "Valves and Valve Gears," Wiley.

The theory of steam engines has been repeatedly written up, but theory without definite rules to follow is of little value to the average practical man. The intent throughout this section has been to avoid theory except where necessary to demonstrate the reason for a given practice.

American marine engine practice has been followed where possible, but where this does not cover the desired ground reference is made to European practice.

CLASSIFICATION AND DEVELOPMENT

Marine Engines Are Classified. (1) According to the arrangement of the working parts as (a) horizontal, (b) inclined, (c) vertical. (2) According to the number of expansions as (a) simple, with one or more cylinders, (b) compound, with two or more cylinders, (c) triple, with three or more cylinders, (d) quadruple, with four or more cylinders. (3) According to the type of propulsion as (a) screw, (b) side-wheel paddle, beam or inclined, (c) stern-wheel paddle, horizontal or inclined. (4) According to the service of the vessel as (a) merchant and (b) naval.

Even though several of the earlier types of marine engines had vertical cylinders, the power was transmitted to the paddle-wheel shaft through a long horizontal beam and a vertical connecting rod and these engines are spoken of as horizontal engines. Inclined engines are used in paddle steamers either of the side-wheel or stern-wheel type. The modern marine screw engine of today is of the vertical type.

Simple engines may be either condensing or noncondensing and may have two or more cylinders working on the same crankshaft. If noncondensing, they are usually spoken of as "high-pressure" engines. Compound engines were originally built with two cylinders, but as the power increased it became necessary for the purpose of construction to use two low-pressure cylinders thus making three-cylinder compound engines. Triple-expansion engines are often made with two low-pressure cylinders to secure better balance and more uniform turning moment. In very large triple-expansion engines, one low-pressure cylinder would be prohibitive on account of its size. Quadruple-expansion engines are not often built with more than four cylinders, but there have been noteworthy installations of large quadruple expansion engines having six cylinders among which may be mentioned the American Line S.S. "St. Paul," and the Hamburg-American S.S. "Deutschland," which have six-cylinder, four-crank quadruple engines with two high-pressure cylinders over the two low-pressure cylinders.

Screw engines operate at much higher revolutions than engines driving paddle wheels and hence differ considerably from paddle-wheel engines owing to the difference in length of stroke.

Merchant and naval engines differ in that no special effort is made in merchant vessels to save weight or space while in naval vessels this is of the utmost importance.

As at present, except in certain types of paddle steamers, horizontal and inclined engines are of historical interest only, this section deals chiefly with the modern, vertical, direct-acting screw engine.

Historical Development of Marine Engines. The earliest marine engines were horizontal, and for a number of years this type was used in war vessels. In these earlier war vessels, which were without armor, protection for the machinery was obtained by placing it below the water line. This fact led to the development of the many curious

displaced its maximum distance to the right; or (on the right side of the piston) when the valve is displaced its maximum distance to the left. **Cutoff** occurs when the valve is displaced as for admission, but is traveling in the opposite direction to that which produces admission. **Release** occurs through a when the valve is displaced by the amount fg of exhaust lap to the left; or through a' when it is displaced by the exhaust lap jk to the right. **Compression** occurs at the same displacements, the directions of valve movement being opposite to those for release. Admission, cutoff, release and compression are described as **critical events.**

Valve and Piston Positions. Usually, the valve will have moved a greater distance than de when the piston has reached the left-hand end of its stroke. The excess of movement over de is called the **lead.** It *is the amount of opening of the steam port when the piston is on the (adjacent) dead center.* There may also be (and usually is) **exhaust lead,** *defined as the* amount of opening of the port on the exhaust side when the piston is at the (more remote) dead center.

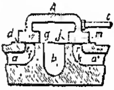

Fig. 1.—Slide Valve.

The valve is moved by an eccentric, equivalent to a crank, the eccentric rod being of great length in proportion to the eccentric throw. Displacements of the valve are therefore regarded as equal to horizontal displacements of the eccentric center, and the **travel** of the valve is equal to **twice the eccentric radius.** If a rocker is used, it may be necessary to write "proportional" for "equal" in these two statements.

With neither laps nor lead, the valve would be central (*i.e.*, in mid-travel) when the piston was at dead center: the two would be 90 deg out of phase. Steam would flow into the cylinder througbout one stroke, and out of it throughout the succeeding stroke. Lap permits cutoff and expansive working. With lap, a 90 deg phase difference between piston and valve would delay admission, and to avoid this disadvantage the phase angle is increased, the valve being displaced from its central position by an amount equal to (lap + lead) when the piston is on dead center. The increase of phase angle is called the **angle of advance**, j. The total phase angle is 90 deg $+ j$.

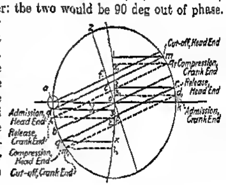

Fig. 2.—Reuleaux Valve Diagram.

Choice of a Valve Diagram. For most purposes, the Reuleaux diagram offers the most convenient method of solving problems connected with a simple eccentric valve gear. The Zeuner diagram is best for Meyer gear, or other double eccentric gears.

The Reuleaux Valve Diagram. (Also called Mueller or Sweet diagram.) In Fig. 2, describe about the center o a circle of horizontal diameter aok, representing the valve travel. Through o draw bo, making the angle $boa = j$; and oz, perpendicular to bo. Lay off oc = lap, op = exhaust lap. Draw af, dcm, qpr parallel to bo. Then the lead is cf, and the four critical events occur at piston-crank positions denoted by the points d, m, r, q. In interpreting these, the large circle is to be regarded as that described by the piston crank, rotating clockwise. The laps are those for the left-hand side of the

and ingenious types of horizontal engines, among which were the **trunk engine** (Fig. 1), the **return connecting-rod engine** (Fig. 2), and the **vibrating or side-lever engine** (Fig. 3).

When the screw propeller first came into use, gearing was used between the slow-turning engine and the propeller shaft to speed up the revolutions in order to obtain proper propeller efficiency.

As the power of marine engines increased, with increase in steam pressure, it soon became evident that marine engines must be vertical in order to be economical in space.

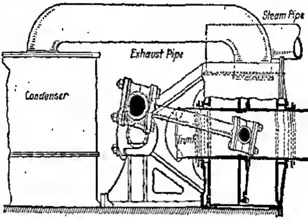

Fig. 1.—Trunk engine.

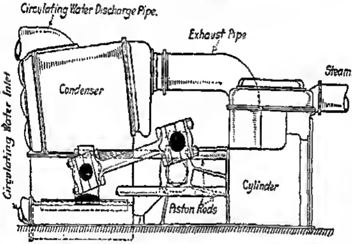

Fig. 2.—Return connecting-rod engine.

Vertical engines were used in merchant vessels long before they were adopted for naval vessels and it was not until the advent of armor which afforded them protection and of high rotative speeds which enabled short strokes to be used that they came into use for all types of naval vessels.

The development of the marine engine is covered briefly by R. H. Thurston in his "Manual of the Steam Engine," in which he says: "The steady rise in steam pressures during the 19th century is best illustrated by naval steam-engineering. In the time of Watt and up to about 1840, the usual pressure in the low-pressure side-wheel engines of that period was from 4 to 7 lb and the rude flue-boilers then in use were of the simplest and weakest forms. By the middle of the century the fire-tubular boiler had come into

valve (*de* and *fg*, Fig. 1) and the crank positions found are those for the critical events referred to that side of the piston which is controlled by the left-hand side of the valve.

On *ka* produced, find the center for an arc *ox*, described through *o*, with radius representing the length of connecting rod to the same scale as *ak* now represents the stroke of the piston. For an engine running "over," this center will be to the left of the diagram. For one running "under," it will be to the right. Then horizontal lines *qx*, *d*3, *m*1, *r*2, represent by their lengths the displacements of the piston from its central position at the critical points, again to the same scale as *ak* represents the piston stroke.

The dotted lines show the construction for the other side of the valve and the other end of the piston. On account of angularity of the connecting rod, the steam distribution is different on the two sides of the piston. Cutoff may be equalized by using different steam laps on the two sides of the valve, but this would lead to inequality of lead. The distance *cz* (Fig. 2) represents the maximum port opening (scale *oc* = lap). Note that (lap + lead) > **exhaust lap**, if release is to occur prior to the end of the stroke.

Examples. 1. Given travel, admission, release, and cutoff. Draw the circle (Fig. 2). Fix points *d* and *m*. Draw *dm*, determining **angular advance.** Fix *r* and draw *rq* parallel to *dm*, determining *q*. Draw *pz* perpendicular to *dm* and *qr*. Then *oc* = **lap**, *op* = **exhaust lap**. Through *a* draw *af* parallel to *dm*. Then *of* = **lead**, *cz* = **maximum port opening.**

2. Given travel, lead, angle of advance, and release. Draw the circle. About *a* draw a circle of radius = lead. Tangent to this circle, draw *dem* making the angle *j* with the horizontal, determining *d*, *m*. Fix *r*, and draw *rq* parallel to *dm*, determining *q*. **Laps** and **maximum port opening** are found as in Case (1).

The Zeuner Diagram. In Fig. 3, draw *jl* horizontally, *AB* vertically, intersecting at *o*; *aok* making the angle *j* with the vertical, and the large circle about *o* of diameter representing the valve travel. On the diameters *ok*, *oa*, describe the small circles. For any crank position 2, the valve displacement is *o*3, determined by drawing the vector *o*2. About *o*, describe arcs *bc*, *de* of radii equal to lap and exhaust lap, respectively. Through the intersecting points *b*, *c*, *e*, *d*, draw radii from *o*, determining

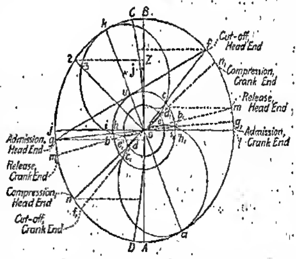

FIG. 3.—Zeuner Valve Diagram.

g, *f*, *m*, and *n* as the critical piston-crank positions. The distance *ih* is the lead, and *uk* is the maximum **port opening.** Piston positions are found as in Fig. 2, by drawing the circular arc *CD* through *o*, and drawing horizontal lines from *g*, *f*, *m*, and *n* to this arc. This construction gives the piston positions for the left-hand (head end) side of the piston in an engine running "over," rotation in Fig. 3 being clockwise. The positions for the crank end are worked out by dotted lines.

quite common use, and pressures had risen to double those above stated. Between 1850 and 1860, the customary pressures in new engines had become 20 to 25 lb, and the introduction of the surface-condenser removing the principal difficulty, the later rise in pressure was rapid and has never ceased. The use of the surface-condenser, by reducing the loss due to the deposition of the calcium sulphate contained in sea water produced a gain of 15 or 20 percent. The type of boiler next made was the cylindrical, Scotch

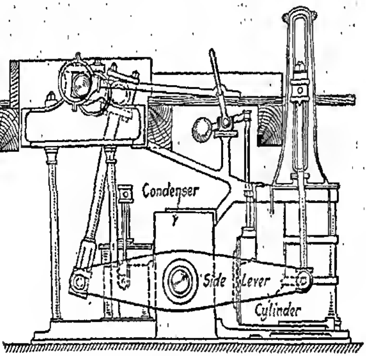

FIG. 3.—Side-lever engine.

form with large flues serving as furnaces and the gases returned through tubes, both flues and tubes enclosed in one cylindrical shell, and the compound engine introduced, the pressures rising rapidly to 60 or 75 lb, these changes resulting in a further economy of 30 or even 40 percent in engines designed during the decade 1860–1870. The next ten years carried pressures for compound engines up to 90 and 120 lb and the triple-

Table 1. Historical Development of the Marine Engine

Date	Type of boiler	Steam pressure, lb gage	Type of engine	Piston speed, fpm
1820	Flue	4-7	Paddle	175
1840	Tubular	10-15		
1850	Flat-sided	20-25	Screw	300
1860	....	30-35	Surface condensing	
1870	Cylindrical	60	Compound	450
1880	....	100		
1885	Water tube	130	Triple	600
1887	....	155		
1890	....	200	Quadruple	700
1900 to date (Merchant)	....	250	Quadruple	900
1900 to date (Naval)	....	300	Four-cylinder triple	1,000

The Zeuner diagram gives valve displacements and port openings for all crank positions in a satisfactory way, but is less accurate than the **Reuleaux diagram** for determining the crank positions at which the critical events occur.

Example. Given cutoff, angle of advance, and port opening. Draw (in Fig. 3) AB, jl, and aok, and the circle on jl, of any convenient radius. Fix f, and draw of. Draw fg perpendicular to aok, determining g. On ok as diameter, describe the small circle, fixing c. About o, describe the arc cb through c, determining h and u. Let p be the required port opening. Then lead $= p\frac{ih}{uk}$; travel $= p\frac{jl}{uk}$; lap $= p\frac{oc}{uk}$.

Crank angles and piston positions for various ratios of connecting-rod length to length of stroke are given on pp. 1006, 1007.

Piston valves may be analyzed as in Figs. 2 and 3, but with "inside edge" distribution the displacement of the valve is (Fig. 1) to the left for admission to the left-hand side of the piston.

FIG. 4.—Multiported Valve.

Multiported valves reduce friction and clearance. Figure 4 shows one form. With a large number of ports, this becomes the **gridiron valve.**

Limits of the Plain Valve. Early cutoff is *impracticable with the plain slide valve.* The point of admission being fixed, hastening of cutoff involves larger lap, earlier release and compression, and either increased travel or reduced maximum port opening. Release can then be delayed by increase of exhaust lap, but this makes compression still earlier.

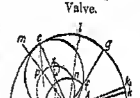

FIG. 5.—Zeuner Diagram for Slide Valve Operated by Shifting Eccentric.

The Shifting Eccentric. In Fig. 5, let ab, cod, ef, and iA be the elements of a Zeuner diagram fixing the four critical events at h, g, k, and j. Let it be required to fix cutoff at l, without change in admission. Draw ol, and om bisecting the angle hol. Find a center, on om, for a circle epn, which shall pass through o and n, the point of intersection of ol and ef. The required conditions are met when epn becomes the valve circle; *i.e.*, when the angle of advance is increased by com and the travel is reduced from cd to $2 \times op$. The symmetrically placed circle on oB now fixes release at k_2 and compression at j_2, the latter event being considerably hastened. Maximum port opening is decreased, but the distribution is superior to that in a plain slide-valve gear.

The **change in throw and angle of eccentric** is accomplished in various ways such as by using a pivoted arm on the flywheel, under governor control. The action may be described by plotting the "path of the eccentric center" cp (Fig. 5). If this path is *straight* and *vertical*, the lead will be constant. If it is *convex* toward o, the travel will be relatively great at late cutoff, and port openings small at early cutoff. Equalization of steam distribution is facilitated when the path is *concave* toward o.

Separate Cutoff Valves. Some of the disadvantages of the plain valve are overcome by employing a second auxiliary mechanism, driven from an independent eccentric, for control of cutoff only, the point of cutoff being varied by hand or by the governor. In the **Meyer valve** (Fig. 6), cutoff occurs (on the left-hand side of the piston) when the auxiliary valve has

expansion engine, coming into use, 1875–1880, the pressure has risen one-fourth or one-third more, this type giving a gain of 15 to 20 percent over the earlier compound engines."

A brief outline of the development of the marine engine is given in Table 1.

Steam Pressure. The earliest marine engines followed land practice and worked with a steam pressure of 4 or 5 lb in a single cylinder with a cut-off of 0.70 to 0.85. Increase in steam pressure was slow, and it was not until about 1880 that 100 lb was reached. The rise in steam pressure was limited by the construction of the boilers on the one hand and by the type of the engine on the other hand. Flat surface or box boilers could not carry pressures over about 30 lb. With the advent of cylindrical boilers (about 1860) the obstacle to the increase in steam pressure from the boiler side was removed. The limit of pressure for single-cylinder engines in the early days was about 50 lb. As compound-, triple-, and quadruple-expansion engines came into use, pressures rose until those in use at the present time were reached. The curve, Fig. 4, shows the increase in steam pressure graphically. Except in radical or freak designs, among which may be mentioned the steam yacht "Arrow," which had a triple-expansion engine built for 350 to 400 lb working pressure, boiler pressures for reciprocating engines have not exceeded 300 lb and this pressure is not likely to be exceeded unless means are found to make use of greater total expansion.

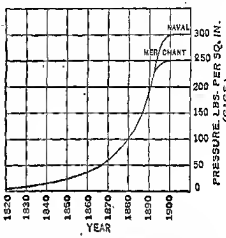

Fig. 4.—Rise in steam pressure.

Pressure Drop. There is always a drop in pressure between the boilers and the throttle valve at the engine, the amount depending on the quality and velocity of the steam, the length of the steam pipe, and the number of bends and valves in the line. For properly designed piping, this drop should not exceed from 5 to 8 lb for merchant work, and from 15 to 20 lb for naval work, the larger drop in naval work being accounted for by the fact that the distance from the boilers to the engines is usually greater, and, in order to reduce pipe sizes and save weight, velocities are higher.

There is also a drop between the main steam pipe and the cylinder through the throttle valve, the engine valves, and the ports. In good designs, this drop should not exceed from 10 to 15 lb in either merchant or naval work.

Pressures in Cylinders and Valve Chests. For the purpose of designing, it is necessary to know the maximum pressure in each cylinder, and the pressures in the valve chests. The maximum pressure in each cylinder occurs at the beginning of the stroke and corresponds to the initial pressure during admission. With slide valves and with piston valves taking outside steam, the pressure on the valve-chest covers corresponds to the initial pressures in the cylinders. For piston valves taking inside steam the pressure on the valve-chest covers corresponds to the pressure of the exhaust from the cylinder

NUMERICAL COMPUTATION

Number of Significant Figures. In any engineering computation, the data are ordinarily the result of measurement and are correct only to a limited number of significant figures. Each of the numbers 3.840 and 0.003840 is said to be given "correct to four figures"; the true value lies in the first case between 3.8395 and 3.8405; in the second case, between 0.0038395 and 0.0038405. The **absolute error** is less than 0.001 in the first case, and less than 0.000001 in the second; but the **relative error** is the same in both cases, namely, an error of less than "one part in 3840."

If a number is written as 384,000, the reader is left in doubt whether the number of correct significant figures is 3, 4, 5, or 6. This doubt can be removed by writing the number as 3.84×10^5, or 3.840×10^6, or 3.8400×10^4, or 3.84000×10^5.

In any numerical computation, the possible or desirable degree of accuracy should be decided on and the computation should then be so arranged that the required number of significant figures, and no more, is secured. Carrying out the work to a larger number of places than is justified by the data is to be avoided, (1) because the form of the results leads to an erroneous impression of their accuracy, and (2) because time and labor are wasted in superfluous computation. The labor of working with six-place tables is nearly three times as great as that with four-place tables. In computations involving several steps, it is desirable to retain one extra figure until just before the final result is reached, in order to protect the last figure against the possible cumulative effect of small tabular errors. **In discarding superfluous figures,** if the first discarded figure is 5 or more, increase the preceding figure by 1. Thus, 3.14159, written correct to four figures, is 3.142; correct to three figures, 3.14. Again, 6.1297, correct to four figures, is 6.130.

Addition. In adding numbers, note that a doubtful final figure in any one number will render doubtful the whole column in which the figure lies; hence all figures to the right of that column are superfluous and contribute nothing to the accuracy of the result.

Subtraction. The "Austrian" or "shop" method is recommended. The mental process is as follows, the figures here printed in boldface type being the only ones written down:

(3 plus how many is 12?) 3 plus **9** is 12; 1 to carry.	14752
(7 plus how many is 15?) 7 plus **8** is 15; 1 to carry.	8463
5 plus **2** is 7. 8 plus **6** is 14.	6289

or the initial pressure in the next cylinder. It is usual to express the initial pressure in the cylinders and the pressure in the valve chests as a percentage of the steam pressure. Table 2 gives the value of this factor for different types of engines, the factors being based on the steam pressure at the engine.

Table 2. Pressures in Cylinders and Valve Chests

P = Boiler Pressure (Gage); $p = P -$ drop from Boiler to Engine

Type of engine	Compound		Triple			Quadruple			
Boiler pressure	125 to 175		175 to 200			200 to 250			
Cylinder	H-p	L-p	H-p	L-p	L-p	H-p	1st I-p	2d I-p	L-p
Initial pressure in cylinders	$0.85p$ to $0.9p$	$0.15p$	$0.9p$ to $0.95p$	$0.3p$ to $0.35p$	$0.03p$ to $0.04p$	$0.9p$ to $0.95p$	$0.35p$ to $0.4p$	$0.1p$ to $0.2p$	$0.01p$ to $0.02p$
Pressure on valve-chest covers for piston valves with outside steam and for slide valves	$0.85p$ to $0.9p$	$0.15p$	$0.9p$ to $0.95p$	$0.3p$ to $0.35p$	$0.03p$ to $0.04p$	$0.9p$ to $0.95p$	$0.35p$ to $0.4p$	$0.1p$ to $0.2p$	$0.01p$ to $0.02p$
Pressure on valve-chest covers for piston valves with inside steam	$0.15p$	3 to 4 lb abs	$0.3p$ to $0.35p$	$0.03p$ to $0.04p$	3 to 4 lb abs	$0.35p$ to $0.4p$	$0.1p$ to $0.2p$	$0.01p$ to $0.02p$	3 to 4 lb abs

Expansion. The number of times the steam admitted to the high-pressure cylinder of a multiple expansion engine up to the point of cut-off, increases in volume up to the point of release in the low-pressure cylinder, is called the **ratio of expansion** or the number of expansions. If there were no clearance, the expansion in the high-pressure cylinder would be the ratio of the total volume swept through by the piston during one stroke, to the volume of the cylinder at the point of cut-off, or $r = 1/b$, r being the expansion in the cylinder and b the cut-off in percent of the stroke. But **clearance** must always be taken into account and its effect is to reduce the expansion in the high-pressure cylinder and hence throughout the engine. The expansion in the high-pressure cylinder, considering clearance, is $r = (1 + c) \div (b + c)$, where c is the clearance volume expressed as a percent of the volume swept through by the piston. The total expansion in a multiple-expansion engine is the expansion in the high-pressure cylinder multiplied by the ratio of the areas of the low-pressure and high-pressure cylinders. This is on the assumption that the point of release in the low-pressure cylinder is at the end of the stroke, which, for all practical purposes, is sufficiently accurate.

Example. Cut-off in the high-pressure cylinder is 0.75, the clearance volume at each end of the high-pressure cylinder is 0.12, and the ratio of the areas of the low-pressure and high-pressure cylinders, 8; the expansion in the high-pressure cylinder, if clearance is disregarded, is $r = 1/0.75 = 1.33$, and the total expansion $1.33 \times 8 = 10.6$. With clearance taken into consideration, $r = (1 + 0.12) \div (0.75 + 0.12) = 1.29$, and the total expansion is $1.29 \times 8 = 10.3$. The reduction in the total expansion of the engine due to this clearance is therefore 3 percent.

As the number of expansions greatly affects the economy of the engine it is of importance, when designing an engine, that the proper expansion be

early cutoff in the high-pressure cylinder increases the total expansion, improves the economy of the engine, and affects the size of the engine for a given horsepower. The cut off in each cylinder after the high-pressure depends on the ratio of its volume to the preceding one. In order to obtain a uniform turning moment, it is desirable to distribute the power equally on the cranks. This distribution may be obtained approximately by varying the cutoffs in the cylinders after the high-pressure by adjusting the valve gear. In a triple-expansion engine, if the cut off in the intermediate-pressure cylinder is increased the back pressure in the high-pressure cylinder is decreased and more power will be developed in that cylinder and less in the intermediate-pressure cylinder. Similarly increasing the cut off in the low-pressure cylinder will reduce the back pressure in the intermediate-pressure and more work will be done in the intermediate-pressure cylinder and less in the low-pressure. The *cutoff usually used in the high-pressure cylinder of different types of engines* is given in Table 3.

Data and Performance of Marine Engines. Table 7 giving the sizes, proportions, and performances of a number of marine engines for vessels of various types will prove useful for reference. Owing to the scarcity of steam consumption data this table lists the engines of several old vessels on which steam consumption tests were made.

Example. Determine the size of a three-cylinder triple-expansion engine for a large cargo steamer to develop 5,000 ihp with 200 lb steam pressure at the boilers and 27 in. vacuum in the condenser. From Table 5 we will select the rpm as 75 and the piston speed as 750 for an engine of this class and ihp. The length of stroke will therefore be $\frac{750 \times 12}{2 \times 75} = 60$ in. The next step is to determine the proper M.R.P. to use in calculating the area of the low-pressure cylinder. Assume a drop of 10 lb from boilers to engine and 15 lb from throttle valve to cylinder. The absolute initial pressure in the cylinder, P_1, will therefore be 190 lb. Assume a back pressure of 4 lb abs. From Table 3 the ratio of the areas of the low-pressure and the high-pressure cylinders for this pressure may be taken as 8.5 and the cutoff in the high-pressure cylinder at full power as 0.75. Table 4 indicates that the clearance in the high-pressure cylinder may be 12 percent. Expansion in high-pressure cylinder $= \frac{1 + 0.12}{0.75 + 0.12} = 1.29$ and total expansion $r = 1.29 \times 8.5 = 11$. Theoretical mep, $P_m = 190 \frac{(1 + \log_e 11)}{11} - 4$. From Fig. 10 the value of $\frac{(1 + \log_e 11)}{11} = 0.31$. Therefore $P_m = 190 \times 0.31 - 4 = 55$. From Table 6 select a card factor of 0.58 as it is well in determining the size of an engine to allow some margin by assuming a safe card factor. M.R.P. then $= 55 \times 0.58 = 31.9$. Area low-pressure cylinder $= \frac{5{,}000 \times 33{,}000}{750 \times 31.9} = 6{,}900$ sq in. and diam $= 94$ in. Area high-pressure cylinder $= 6{,}900 \div 8.5 = 810$ sq in. and diam $= 32$ in. If the diameter of the intermediate-pressure cylinder is taken 54 in., the ratios of successive cylinders will be 2.85 and 3.03.

PROPORTIONING OF ENGINE PARTS

Throughout this section the details of the engine are proportioned by the calculation of pressures, stresses, and factors of safety as is done by the practical designer rather than by rules and empirical formulas. As reciprocating engines are no longer being designed for the fighting ships of the Navy, the

selected to suit the other conditions. The total expansion to use in design depends upon the boiler pressure, the cut-off in the high-pressure cylinder, and the ratio of the areas of the low-pressure and high-pressure cylinders. The total expansion in the best present-day practice in marine engines is given in Table 3. The **total expansion is approximately** absolute initial pressure in the high-pressure cylinder ÷ 22, 17.5, and 16 for compound-, triple-, and quadruple-expansion engines.

Table 3. Total Expansions for Different Types of Marine Engines

Type of engine	Boiler pressure, lb gage	Cut-off in h-p cylinder, percent	Ratio of l-p to h-p cylinder	Total expansion
Compound	125–175	0.65–0.75	4–5	5.5–7.5
Triple (merchant)	175–200	0.70–0.77	7.5–8.5	9.5–11
Quadruple	200–250	0.65–0.72	9–12	12–15

Back Pressure. The term "back pressure" is usually applied to the pressure of the exhaust from the low-pressure cylinder, although of course there is back pressure in the other cylinders due to the exhausting of the steam into the next cylinder. It is of importance to keep the back pressure in the low-pressure cylinder as low as possible as this pressure acts on the piston in opposition to the steam pressure. In order to keep the back pressure low, care should be taken in the design of the low-pressure cylinder to make the exhaust passages and exhaust pipes of ample area and free from obstructions and abrupt turns. The back pressure in a well-designed low-pressure cylinder **should not exceed 3 to 4 lb abs.** It may be found from the indicator card and is usually about 2 lb more than the pressure in the condenser as shown by the vacuum gage.

Vacuum. In recent years, considerable attention has been paid to the design of condensing apparatus in order to obtain a higher vacuum. Formerly it was the belief among many chief engineers that there was no gain in economy in working with a vacuum over 24 or 25 in. (5 or 6 in. Hg abs), with the accompanying low temperature of air-pump discharge water, as in many merchant steamers there is not enough exhaust steam from auxiliaries properly to heat the feed water. A high vacuum may reduce the steam used by the main engine, but when the total heat used is taken into consideration, in case of insufficient auxiliary exhaust steam to heat the feed water, the fuel consumed may actually increase. There is a limit to the vacuum to which existing engines, designed without special attention being paid to exhaust ports and passages, will respond, and any increase in vacuum over about 25 in. may actually prove a loss owing to the increase in power required for air and circulating pumps.

Clearance. **Volumetric clearance** is the volume enclosed between the piston and the valve face at the beginning of the stroke and is expressed as a percentage of piston displacement. This percentage varies with the size of the engine, the ratio of diameter to stroke, the location of the valves, and the size and length of ports. The percentage of clearance is greater in a fast running engine, as the ports are made larger to avoid excessive steam velocities. The **actual clearance volumes** of an engine are found by measuring the amount of water or other liquid required to fill the clearance spaces.

Clearance volume may also be calculated from the engine drawings with a fair degree of accuracy. **Linear or piston clearance** (see p. 1077) is the distance between the piston and the cylinder at each end and may account for only a small part of the volumetric clearance. The steam in the clearance space does no work except during expansion and, as it is not practicable to carry compression completely to admission pressure, a certain amount of *fresh steam must be supplied each stroke to fill the clearance space; clearance* therefore **increases steam consumption.** Clearance also **reduces the ratio of expansion** (see p. 1057) and consequently **reduces the work** done per pound of steam.

Although clearance should be kept as small as possible, a certain amount is necessary at each end of the cylinder to provide space for the water which may be condensed when starting the engine, or which may be carried over from the boilers. By keeping the valves close to the cylinders and making the ports horizontal the values given under "short ports" in Table 4 may generally be realized.

Table 4. Volumetric Clearances in Percent of Piston Displacement

	Short ports	Medium length ports	Very long ports
H-p cylinders with piston valves	10–12	16–18	22–26

L-p cylinders with slide valves	6–8	8–10	12–14

EFFICIENCY

Thermal

The transformation of heat energy into mechanical energy or work is accomplished by a series of processes called a cycle, during which the working fluid passes through successive states of pressure, volume, and temperature, which, after completion, leaves it in its initial state. The efficiency of a cycle is the ratio of the heat energy converted into useful work to the heat energy supplied.

The **Carnot cycle** as shown in Fig. 5 consists of two isothermal lines *ab* and *cd* representing the application and rejection of heat at constant temperature and two adiabatic lines *bc* and *da* representing expansion and compression without transmission of heat to or from the fluid. It is impracticable to construct an engine to operate on this cycle, but it is important as being the most efficient cycle. The efficiency of the Carnot cycle, $E_c = (T_h - T_c) \div T_h$, where T_h and T_c are the absolute temperatures of the steam at admission and exhaust, respectively.

The **Rankine or ideal cycle** more nearly approaches the cycle of events in an actual engine. An engine operating on this cycle, Fig. 6, would receive vapor at constant pressure (*ab*), expand adiabatically to exhaust pressure (*bc*), exhaust against constant back pressure (*cd*), and compress adiabatically to admission pressure (*da*). In such an engine the exhaust valve would not open until expansion is complete, the walls would be nonconducting, there would be no friction, no leakage past the valves or the piston, and no drop in pressure through the throttle, admission, and exhaust valves. The efficiency

of the Rankine cycle, $E_r = q_r \div q$, where q_r is heat converted into work by this cycle (adiabatic or isentropic heat drop) and q is heat supplied.

In the actual engine however the above conditions are not realized and the actual efficiency is much less than the ideal. The **actual thermal efficiency,** $E_a = q_a \div q$, where q_a is heat converted into work by the actual engine.

It is usual to compare the actual efficiency of an engine with the efficiency of the Rankine or ideal engine. This is called the cylinder efficiency or efficiency ratio, $E_r \div E_a = q_a \div q_r$, and is the ratio of the heat converted into work in the actual engine to the heat which an ideal engine (Rankine cycle) operating with the same admission and exhaust pressures, could transform into work.

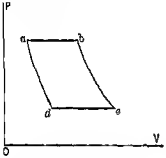

FIG. 5.—Carnot cycle for steam.

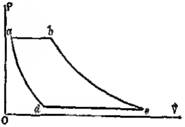

FIG. 6.—Rankine cycle.

All the above efficiencies are based on 1 lb steam, and the heat supplied to the steam, q, is the heat supplied by the boiler and the feed-water heater above the heat of the liquid at exhaust pressure.

Example. The steam consumption of a marine engine at full power is 14 lb per ihp-hr. The pressure in the main steam pipe is 200 lb gage with 50 deg superheat and the vacuum is 27 in. Find (a) Carnot efficiency, (b) Rankine or ideal efficiency, (c) actual efficiency, and (d) efficiency ratio.

(a) Absolute temperature of steam at 200 lb gage and 50 deg superheat, $T_h = 438 + 460 = 898$ deg. Absolute temperature of steam at 27 in. vacuum, $T_e = 115 + 460 = 575$ deg F.

$$\text{Carnot efficiency} = \frac{898 - 575}{898} = 0.36$$

(b) The adiabatic heat drop from 200 lb gage and 50 deg superheat to 27 in. vacuum is best found from an entropy chart.

		Btu
Heat content of steam at 200 lb gage and 50 deg superheat	=	1232
Heat content of steam at 27 in. and same entropy	=	901
Isentropic heat drop, q_r	=	331
Heat content of steam at 200 lb gage and 50 deg superheat	=	1232
Heat content of water at 27 in. vacuum (115–32 deg)	=	83
Heat supplied, q	=	1149

$$\text{Rankine or ideal efficiency} = \frac{331}{1149} = 0.29$$

$$\text{(c) Btu per hp-hr} = \frac{33{,}000 \times 60}{778} = 2545$$

proportions given here are for engines of merchant vessels or of naval auxiliary vessels, which, when using reciprocating engines, follow merchant practice.

Stresses in marine engines are kept low, and large **factors of safety** are used to make the engines safe against the strains caused by rolling and pitching. Furthermore, low stresses and massive parts guard against breakdowns at sea with their accompanying dangers and delays.

Indicated and Effective Thrust. It is usual in designing thrust bearings for reciprocating engines to base the stresses and pressures on the indicated thrust and the proportions of thrust bearings in this section are on this basis. The actual or effective thrust may be found by multiplying the indicated thrust by 0.55 which is the combined efficiency of engine and propeller, assuming the efficiency of the propeller 65 per cent and the mechanical efficiency of the engine, including shaft bearings and attached pumps, 85 per cent.

Destructive Loads for Columns. The sizes of piston rods, connecting *rods, and other parts acting as struts are determined by treating them as* columns. This involves the ratio of length (L) to radius of gyration (ρ), and the destructive load for the material of which the part is made. The column calculation may be greatly simplified by the use of Table 8, giving the destructive loads for various values of $L \div \rho$ for different classes of material. These values are based on the results of an extensive series of experiments on iron and steel struts made by the Pencoyd Iron Works and published in their handbook. The steel used in merchant engines averages about 70,000 lb ultimate tensile strength, and this value is used in the safe stresses and factors of safety given in this section. These figures should be corrected if steel of different ultimate tensile strength is used.

Table 8. Destructive Loads for Iron and Steel Struts
(Adapted from Pencoyd's Handbook)
L = Length of column in in. ρ = Radius of gyration in in.

$\frac{L}{\rho}$	Wrought iron or soft steel of about 46,000 to 55,000 lb tensile strength			Medium steel of about 70,000 lb tensile strength			Hard steel of about 100,000 lb tensile strength

Actual heat turned into work, per lb steam, $q_a = \frac{2545}{14} = 182$ Btu

Actual efficiency $= \frac{182}{1149} = 0.16$

(*d*) Efficiency ratio $= \frac{0.16}{0.29} = \frac{182}{331} = 0.55$

Aside from improvement in mechanical features the efficiency of an engine may be increased by (1) increasing the initial steam pressure; (2) reducing the back pressure; (3) reducing condensation and reevaporation in the cylinder by (*a*) superheating, (*b*) steam jacketing, (*c*) compounding.

The effect of increasing initial pressure and reducing back pressure is illustrated by the curves in Fig. 7. It will be noted that a large increase in initial pressure is required to produce an effect equal to a small reduction in back pressure.

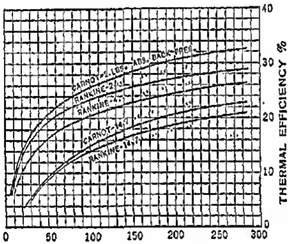

FIG. 7.—Carnot and Rankine efficiency with dry saturated steam.

Cylinder Condensation and Reevaporation. The following treatment of this subject is from Barton's "Naval Engines and Machinery," U.S. Naval Institute: Excepting the loss of heat to the condenser in the exhaust steam, initial condensation in the cylinders is the most serious loss connected with the use of steam as a working medium. During admission, expansion, and exhaust, there is a complex interchange of heat between the cylinder walls and the steam, greatly increasing the steam consumption and reducing the efficiency. Steam at admission comes in contact with the metallic surfaces of the cylinder walls which have been chilled by contact with the cool steam of expansion and exhaust of the previous stroke. Condensation immediately commences and continues until the temperature of the cylinder walls approaches that of the steam. Since the throttle is still open, fresh steam is supplied to take the place of the steam liquefied, so that at the point of cut-off, much more steam has been supplied than corresponds to the volume of the admission space. After cut-off the deposited moisture and water begin to reevaporate as soon as the temperature of the steam falls below that of the cylinder walls, and the weight of the steam present in the cylinder as steam

Section modulus is required in the calculation of bending stresses and, as the sections of the parts of engines figured as beams are usually complicated, the method of finding the section modulus is presented.

The moment of inertia and section modulus of a compound section may be obtained by treating it as a combination of elementary sections of which the properties are already known or can be found. The first step is to find the center of gravity, which, in the case of a symmetrical section, is at the center of the figure. For an unsymmetrical section the center of gravity is determined by multiplying the areas of the component parts by the distances of their centers of gravity from an assumed axis, and dividing the sum of these products by the sum of the areas, which gives the distance of the center of gravity of the whole section from the assumed axis. The moment of inertia of the compound section about an axis through its center of gravity is the sum of the moments of inertia of each component part about an axis through its own center of gravity parallel to the axis of the compound section, plus the sum of the products of each area by the square of the distance of its center of gravity from the axis through the center of gravity of the compound section. The section moduli for tension and compression are obtained by dividing the moment of inertia of the whole section by the distances from the neutral axis

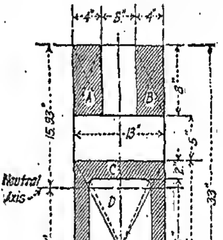

FIG. 11.

Table 9. Method of Finding Section Modulus of a Compound Section

Element	Width (b)	Height (h)	Area (A)	Distance c.g. of element from HK (l)	Moment ($A \times l$)	Moment of inertia about its own axis I_x	Distance from c.g. of element to neutral axis ($l - d = D$)	AD^2

d = Distance of center of gravity above assumed axis HK = $3021 \div 177 = 17.07$ in. I_x of rectangular section $= Ah^2 \div 12$. Total moment of inertia I of section $= I_x + AD^2 = 6463 + 13,385 = 19,848$. Y_t = distance to extreme fiber in tension = 17.07 in. Y_c = distance to extreme fiber in compression = 15.93 in. Z_t = section modulus (tension) $= I \div Y_t = 1163$. Z_c = section modulus (compression) $= I \div Y_c = 1245$.

gradually increases toward the end of the stroke. This heat transferred to the steam by reevaporation during expansion and before exhaust does a small amount of work on the piston, but the heat transferred to the steam during exhaust goes directly to the condenser thus increasing the already large exhaust loss. In general in a single cylinder, condensation and loss from reevaporation are increased by an increase in the range of temperature between admission and exhaust.

Superheat. The practical advantages of superheated steam are primarily due to the reduction of the losses caused by cylinder condensation. If the steam is kept dry to the point of cut-off, these losses are practically eliminated. This would probably require higher superheat than is otherwise desirable in marine work. In early days with the very low boiler pressures in use, considerable gain in economy resulted from the use of superheated steam as a large quantity of heat could be added without increasing the temperature to a dangerous extent. As boiler pressures rose to about 60 lb, the total temperature became too high for the construction and materials then in use and superheat was discontinued on the ground that the high temperature dried up the unguents, destroyed the packing in the stuffing boxes (metallic packing was unknown), and caused excessive wear in the cylinders. Later on, however, the use of superheat in marine engines was revived and during the past 20 years there have been many successful installations using moderate and high superheat in both merchant and naval vessels. There is about 1 per cent increase in economy for each 10 deg F of superheat.

As steam at high temperature has a chemically corrosive effect on all brass and copper besides causing other troubles, the present tendency with reciprocating marine engines is to use moderate superheat (not exceeding 100 deg F) to ensure dry or slightly superheated steam at admission.

With saturated steam the cylinder walls are lubricated by the condensed steam and by the oil entering the cylinder from the use of oil swabs on the rods, but with superheated steam oil lubrication must be supplied and this oil must be removed from the feed water before it enters the boilers. On account of the high temperature special metallic packing is required at least for the piston rods and valve stems of the high-pressure cylinder.

Steam Jackets. By constructing the cylinder with jacket spaces and filling these spaces with live steam, cylinder condensation may be reduced. The jacket steam, to be effective, must be kept in circulation, and this causes a loss by condensation in the jackets which may entirely offset the gain produced by the prevention of condensation within the cylinders. Tests made to determine the economy of steam jackets have usually indicated some gain. However, it is doubtful if in everyday practice there is much economy in the use of steam jackets on account of general defects in the system and lack of attention by the engineers. Also in large engines the thickness of the walls interferes with the rapid interchange of heat. But even if there be no economy in the use of steam jackets, the jacket provides a method of warming the cylinders before starting up. At present, steam jackets are very seldom used in merchant engines and, when used, only those cylinders are jacketed which are fitted with liners which provide the jacket spaces. In naval work it is the practice to jacket all cylinders. In order to prevent excessive condensation in the jackets, jacket steam for intermediate- and low-pressure cylinders should be reduced to a pressure corresponding to the temperature of admission steam within the cylinders.

of the extreme fibers on the tension and compression sides. Table 9 gives the calculations for the moment of inertia and section moduli for the section shown in Fig. 11.

Unbalanced Load. The unbalanced load (*P*) on the high-pressure piston is taken as the basis for proportioning and calculating the strength of the piston rods, crossheads, connecting rods, and housings and for calculating the pressure on the crosshead pins, crosshead slippers, crankpins, and main bearings. The unbalanced pressure is the difference in the absolute pressure on the opposite sides of the piston at the time of admission and is found from the indicator card. The unbalanced load then is the area of the cylinder multiplied by the unbalanced pressure. The unbalanced loads in the

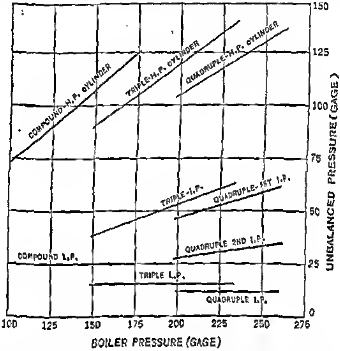

Fig. 12.—Unbalanced steam pressures in marine engines.

different cylinders vary with the ratios of the cylinders and the valve setting, the load on the intermediate-pressure piston of a triple expansion and on the 2d intermediate-piston of a quadruple expansion engine being higher than the load on the high-pressure piston, but for all practical purposes the high-pressure unbalanced load may be used for all cylinders. The unbalanced pressure in all cylinders except the low-pressure vary with the boiler pressure, and the curves in Fig. 12, taken from the indicator cards from a number of engines, show the unbalanced pressures in the cylinders for different boiler pressures. The piston rods, crossheads, and connecting rods are usually made the same size for all cylinders. For the purpose of calculating the strength of these parts for the low-pressure cylinders of four-cylinder triple-expansion engines, it is advisable to assume the unbalanced load in these cylinders as 60 per cent of the unbalanced load in the high-pressure cylinder as the actual unbalanced load often runs higher than the theoretical 50 per cent.

Compounding. To obtain the full benefits of high pressures and large ratios of expansion, it is necessary that the expansion be carried out in two or more cylinders in order to reduce cylinder condensation by reducing the range of temperature in each. Furthermore, the steam reevaporated during the exhaust stroke in one cylinder is available for expansion in the next instead of passing directly to the condenser. The usual pressure ranges for compound-, triple-, and quadruple-expansion engines are given in Table 3.

Mechanical

The **mechanical efficiency** of an engine is the ratio of the horsepower developed in the cylinders, ihp, to the horsepower delivered to the shaft, shp, as determined by the use of torsion meters. The difference between the two is the **frictional loss.** The mechanical efficiency of marine engines varies from 0.90 to 0.93 at full power to 0.94 to 0.95 at low powers. Bauer, in "Marine Engines and Boilers," cites several marine engines in which the mechanical efficiency runs from 0.91 for a 1,640 ihp engine to 0.935 for one of 4,500 ihp. Archibald Denny in a paper read before the Institution of Naval Architects, March, 1907, gives a curve of mechanical efficiency of a certain marine engine which shows values of about 0.925 at 1,325 ihp, 0.937 at 400 ihp and 0.947 at 230 ihp. The mechanical efficiency of **engines with attached pumps** will be at least 5 percent lower than the above figures.

Steam Consumption. It is usual to rate the economy of marine engines in terms of steam consumption per ihp-hr. In general, the steam consumption per ihp will be lower for engines with high ratios of expansion if properly proportioned as to ratios of cylinders, cut-off, clearance, etc., than for engines with low ratios of expansion. Other considerations which improve economy are superheating, lubrication, good workmanship and alignment, and proper care and operation. Very few tests of steam-consumption of reciprocating merchant engines have been made and published but Table 7 gives the steam consumption of several merchant and naval engines of different types.

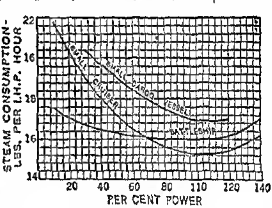

FIG. 8.—Characteristic reciprocating-engine steam-consumption curves.

The steam consumption per ihp **increases as the power decreases.** It is also usually **higher at overload than at designed full power.** These characteristics are shown by the curves in Fig. 8, in which steam consumption per ihp is plotted against per cent of power, calling designed full power 100 per cent. The steam consumption per ihp of merchant engines, which are proportioned to meet the conditions given in Table 3, exclusive of auxiliaries, is approximately as follows: compound 500 to 1,000 ihp, 18 to 22 lb; triple 1,000 to 2,000 ihp, 16 to 17 lb; 3,000 to 6,000 ihp, 15 to 16 lb; quadruple 2,000 to 4,000 ihp, 12.5 to 13.5 lb. The use of superheat should reduce these values about 1 per cent for each 10 deg.

Cylinders

Cylinder Liners and Barrels. The cylinder barrel, bottom, and valve chest are cast in one piece which makes a complicated casting. For this reason a good quality of close-grained cast iron that will run easily must be used. This quality of cast iron does not resist the wear of the piston rings as well as will a harder iron but hardness must be sacrificed to ensure a sound casting. On account of the high pressure and temperature in the high-pressure cylinder it is more liable to fracture and wear than are the other cylinders and so it is customary to fit this cylinder with a close-grained cast-iron liner as hard as can be conveniently machined. In merchant practice, it is not usual to fit liners in low-pressure cylinders, but they are often fitted in intermediate-pressure cylinders. Some owners, however, prefer to have liners in all cylinders to lessen the cost of renewal in case of fracture or serious wear of the cylinder bore.

Figure 13 shows a **h-p cylinder** with a **piston-valve chest** and with straight and direct ports. This gives a much smaller **volumetric clearance** than is possible with the long curved ports formerly used. It will be noted that the top and bottom of the valve chest extend above and below the cylinder, but this is less objectionable than large clearances. The space between the liner and the cylinder is made small to reduce to a minimum the volume for steam in case the joints between the liner and the cylinder leak. For examining the valve laps without removing the top valve-chest cover, inspection holes fitted with covers are provided on the side of the valve chest in line with the top and bottom steam ports.

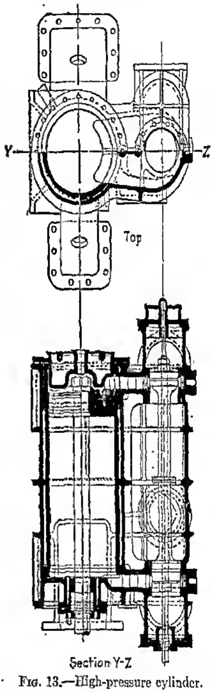

FIG. 13.—High-pressure cylinder.

Figure 14 shows a **low-pressure cylinder** from another engine with a **double-ported slide-valve chest** and with the ports as short and direct as is possible with this type of valve. The volumetric clearance is small and the slide valve permits the top of the valve chest to come in line with the top of the cylinder. A manhole in the bottom allows access.

DETERMINING SIZE OF THE ENGINE

Size of Low-pressure Cylinder. As the low-pressure cylinder must be of sufficient size to pass all the steam used by the engine at terminal pressure it is logical, in determining the size of an engine for a given horsepower, that the diameter of the low-pressure cylinder be determined first. The length of the stroke, revolutions or piston speed (P.S.), and the mep referred to the low-pressure cylinder (M.R.P.) must first be selected. Then area low-pressure cylinder in sq in. $= \frac{\text{ihp} \times 33{,}000}{\text{P.S.} \times \text{M.R.P.}}$. The diameters of the high-pressure and low-pressure cylinders are determined by the ratios of their areas to the area of the low-pressure cylinder.

Length of stroke is chosen to suit the size of the engine and the conditions under which it is to operate and is ordinarily 0.6 to 0.7 of the diam of the low-pressure cylinder. When there are two low-power cylinders, this factor refers to the diam of one equivalent cylinder.

Revolutions per minute (rpm) also vary with the size of the engine and the class of service. Table 5 gives the revolutions and piston speed generally adopted for reciprocating engines for vessels of various types. Piston speed (P.S.) in ft per min $= \frac{\text{rpm} \times \text{stroke} \times 2}{12}$

Table 5. Revolutions and Piston Speed of Reciprocating Engines

Type of vessel	Rpm	Piston speed, fpm
Tugboats and other small craft	100–200	400–550
Screw river and bay steamers	100–150	500–700
Large passenger steamers	75–100	700–1,000
Large cargo steamers	70–85	550–750
Small cargo steamers	65–85	500–700
Beam paddle-wheel engines	15–35	400–700
Inclined paddle-wheel engines	35–60	400–700

Mean Referred Pressure (M.R.P.). In a multiple-cylinder engine the mean referred pressure is the mep that would be required if the work of all the cylinders was done in the low-pressure cylinder. $\text{M.R.P.} = \frac{\text{ihp} \times 33{,}000}{\text{area l-p} \times \text{P.S}}$. The area of the piston rod is not deducted. The M.R.P. is always calculated when the power of an engine is determined from indicator cards as a means of comparison with other engines, and it is also used in determining the size of the low-pressure cylinder of a multiple expansion engine. The designer in determining the M.R.P. must properly coordinate the factors upon which the M.R.P. depends, *viz.*; the cutoff in the high-pressure cylinder, the initial steam pressure, the back pressure, and the ratio of the areas of the low-pressure and high-pressure cylinders. The initial pressure in the high-pressure cylinder depends upon the drop in pressure between the boilers and the cylinder as discussed on p. 1056. Back pressure in the low-pressure cylinder has also been discussed on p. 1058. The M.R.P. to suit the given conditions is found by calculating the theoretical mep and

multiplying this by the **card factor.** The mean referred pressures for engines of different types are given in Table 7.

Theoretical Mean Effective Pressure. This is the mean pressure of admission and expansion as shown by the theoretical diagram in Fig. 9. This diagram represents the pressure and volume of the steam admitted to the high-pressure cylinder, the expansion through all the cylinders, the volume of the steam at release, and the theoretical pressure at exhaust. It is usual to assume that the steam expands in accordance with the law pv = constant in which case the expansion curve is hyperbolic and the theoretical mep,

$$P_{m_t} = P_1 \frac{(1 + \log_e r)}{r} - p_b$$

in which P_1 is absolute initial pressure, r is total expansion, and p_b absolute back pressure. To simplify the calculation the values of $\frac{1 + \log_e r}{r}$ for different values of r may be taken from the curve in Fig. 10. In calculating P_m it is advisable to use a drop of about 10 lb between the boilers and the engine and a drop of about 15 lb from the throttle valve to the cylinder for the ordinary arrangement of machinery and piping.

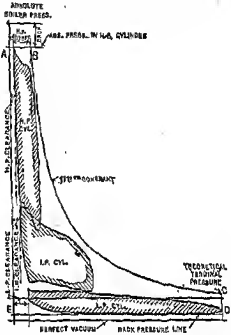

Fig. 9.—Combined actual and theoretical indicator diagram for a triple-expansion engine.

With these assumed drops the absolute initial pressure, P_1, will be 10 lb less than the boiler pressure by gage. Ordinarily a back pressure of 4 lb abs may be assumed. The value of r is calculated as shown on p. 1057.

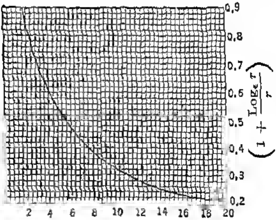

Fig. 10.

Card Factor. The ratio of the areas of the actual indicator cards to the theoretical combined card $ABCDE$ as shown in Fig. 9 or the ratio of the actual mean referred pressure to the theoretical mep (M.R.P. $\div P_m$) is called the "card factor." This factor represents the losses due to cylinder condensation, drop in pressure through ports and passages, and all other losses between the heat available in the steam and the

Thickness of Liners and Barrels. In determining the thickness of liners and of cylinders without liners, allowance is always made for reboring. The following formula, in which P = boiler pressure, D = diam in in., f = allowable fiber stress, and c = a constant for reboring, is used in determining the thickness of high-pressure cylinders and liners: thickness $= (P \times D) \div 2f + c$. The constant c is usually taken as $\frac{1}{8}$ in. and the stress is kept low; 1,500 lb for small and 2,500 lb for large high-pressure cylinders is good practice. In determining the thickness of cylinder barrels in which liners are fitted, the same formula and the same stress are used but no allowance is made for reboring; in this case D = the actual cylinder-barrel diameter. The thicknesses of different sizes of high-pressure cylinder liners and of cylinders fitted with liners for a steam pressure of 200 lb are given in Table 10. For pressures above or below 200 lb the thickness should be increased or decreased accordingly. It is usual to make the thickness of cylinders and liners for the other cylinders the same as the high-pressure. In designing cylinders much depends on the judgment of the designer in giving due consideration to factors such as the minimum thickness of a large cylinder to ensure a sound casting, the ribbing of flat surfaces, and the avoidance of lumps of metal which may cause cracks or spongy spots in the casting. Table 11 gives the thickness of low-pressure cylinders with and without liners.

Table 10. Thickness of H-p Cylinders Fitted with Liners
For 200 Lb Steam Pressure

Diam of bore	Thickness cylinder	Thickness liner
15	$1\frac{1}{16}$	$1\frac{3}{16}$
20	$1\frac{1}{8}$	$1\frac{1}{4}$
25	$1\frac{1}{4}$	$1\frac{3}{8}$
30	$1\frac{3}{8}$	$1\frac{1}{2}$
35	$1\frac{1}{2}$	$1\frac{5}{8}$
40	$1\frac{5}{8}$	$1\frac{3}{4}$

Table 11. Thickness of L-p Cylinders

Diam of bore	If liner fitted	If no liner fitted
40	1	$1\frac{1}{8}$
50	1	$1\frac{3}{16}$
60	$1\frac{1}{8}$	$1\frac{5}{16}$
70	$1\frac{1}{8}$	$1\frac{3}{8}$
80	$1\frac{1}{4}$	$1\frac{1}{2}$
90	$1\frac{3}{8}$	$1\frac{5}{8}$
100	$1\frac{1}{2}$	$1\frac{3}{4}$
110	$1\frac{5}{8}$	$1\frac{7}{8}$

Thickness of Cylinder Walls. Representing the thickness of metal in the cylinder without liners by t, the thickness of the different walls of the cylinder may be taken as follows: thickness of metal in bottom $= t$; in steam ports and valve chest $= 0.85t$; in slide-valve face $= 1.3t$; in cylinder feet $= t$ to $1.1t$; in ribs in cover or bottom $= t$.

The cylinder bottom should be strongly ribbed and a good connection made to the cylinder feet as the unbalanced load is transmitted through the

heat actually converted into work in the cylinders. This factor varies with the number of cylinders in which expansion takes place, and various other considerations. . For the usual ratios of cylinders and total expansions the values in Table 6 may be used for saturated steam. Methods of calculating

Table 6. Ratio of Actual to Theoretical Mean Referred Pressure (Card Factor)

Type of engine	Card factor
Single-cylinder, l-p paddle engines	0.68–0.72
Two-cylinder, compound paddle engines	0.62–0.66
Two-cylinder, small compound screw engines	0.58–0.66
Three-cylinder, triple-expansion merchant engines	0.58–0.63
Four-cylinder, triple-expansion merchant engines	0.57–0.62
Four-cylinder, quadruple-expansion merchant engines	0.60–0.64

card factors differ in that P_1 is sometimes taken as the boiler pressure and sometimes the back pressure and clearance are neglected. With superheat the specific volume of the steam is increased and larger cylinders are required for the same power. It therefore follows that smaller card factors must be used. Data from actual engines show that the card factor is reduced approximately 1 per cent for each 10 deg of superheat. The use of steam jackets increases the card factor.

Ratios of Cylinders. The ratio of the areas of the low-pressure and high-pressure cylinders of a multiple-expansion engine must be taken into consideration in connection aith the total ratio of expansion. The ratios for different boiler pressures and ratios of expansion for well-proportioned marino enginos are given in Table 3. The ratios of the areas of successive cylinders, in connection with the cutoff in each cylinder, affect the power distribution in the different cylinders. In practice it is usual to determine the sizes of the intermediate cylinders more or less arbitrarily and proportion the cutoffs to suit the ratios. In triple-expansion engines the ratio of the areas of successive cylinders is approximately $\sqrt{\text{area l.p.} \div \text{area h.p.}}$ and in quadruple engines approximately $\sqrt[3]{\text{area l.p.} \div \text{area h.p.}}$ However, it is usual to increase somewhat the ratios of the areas of successive cylinders, toward the low-pressure cylinder, approximately as follows:

	$\frac{\text{1st i-p}}{\text{h-p}}$	$\frac{\text{2d i-p}}{\text{1st i-p}}$	$\frac{\text{L-p}}{\text{2d i-p}}$	$\frac{\text{L-p}}{\text{H-p}}$
Triple	2.65–2.8		2.85–3.0	7.5–8.5
Quadruple	2–2.2	2.1–2.3	2.2–2.4	9–12

The ratios of cylinders for engines of different types are given in Table 7.

Cutoff. The cutoff in the high-pressure cylinder regulates the total horsepower of the engine, and the cutoff in the other cylinders regulates the distribution of power in the different cylinders. Decreasing the high-pressure cutoff decreases the total power as less steam is admitted per stroke. Similarly increasing the high-pressure cutoff increases the total power. An

feet to the engine framing. Sometimes for very large cylinders or when jackets are used, the bottom is made double. In large cylinders a manhole is fitted in the bottom for access as shown in Fig. 14.

Water Testing of Cylinders. After the cylinder castings are machined, they should be tested by water pressure for strength and soundness as follows: high-pressure cylinders to 1.5 times the boiler pressure, intermediate-pressure cylinders to 1.5 times the initial pressures given in Table 2, and low-pressure cylinders to 25 lb.

Steam ports are made as **wide** as practicable to keep the **height** a minimum and thereby reduce the valve travel. The area is determined by the steam velocities given in Table 13. The steam ports are made as **short and direct** as practicable to keep the volumetric clearance small and to reduce resistance and condensation. Abrupt turns and projections in the ports should be avoided.

Cylinder Bolting. Cylinder cover studs vary from 1⅛ in. for a 15-in. cylinder to 1¾ in. for a 40-in. high-pressure cylinder. Valve-chest cover

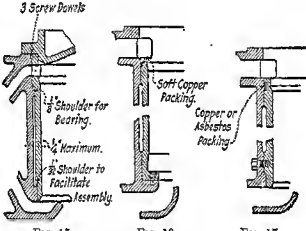

FIG. 15. FIG. 16. FIG. 17.
Methods of securing cylinder liners.

studs vary from 1 to 1½ in. for the same size cylinders. One size of studs is used for all cylinder covers and one size for all valve-chest covers in the same engine. **Pitch of studs** in diameters to ensure tight joints should not exceed: 3 to 4 for high-pressure, 4 to 5 for intermediate-pressure, and 5 to 6 for low-pressure cylinders. The stress in the studs should be based on the initial pressures in the cylinders and valve chests given in Table 2. Stresses should not exceed 3,000 lb for small and 5,500 lb for large studs. **The flanges for cylinder and valve-chest covers** should be 2.6 to 2.8 times the diameter of the studs in width and 1.4 to 1.8 times the diameter of the studs in thickness. For **bolting in the feet** see p. 1083.

Securing Cylinder Liners. It is very difficult to make joints between the cylinder and the liner which will remain steamtight after the engine is in commission. It is therefore important that the space between the cylinder and the liner, which may be filled with steam, be reduced to a minimum. Figure 15 shows a liner supported by a shoulder turned near the upper end. The liner extends to the top of the cylinder and is held in place by the cylinder

This method is especially useful when it is desired to subtract from a given number the sum of several other numbers.

7 plus 1 is 8; plus 5 is 13; plus 9 is 22; 2 to carry.	14752
5 plus 0 is 5; plus 2 is 7; plus 8 is 15; 1 to carry.	3125
3 plus 1 is 4; plus 1 is 5; plus 2 is 7.	101
5 plus 3 is 8; plus 6 is 14.	5237
	6289

The use of a wavy line to indicate subtraction is also recommended, as it will minimize the danger of adding when subtraction is intended.

Multiplication. In long examples in multiplication, the arrangement of work here illustrated is recommended, since it facilitates the abbreviation of the work by the omission, in practice, of all the figures on the right of the vertical line.

41492|xxx
```

The **position of the decimal point** should be determined by reference to the first, or left-hand, figures of the numbers, rather than by "pointing off" so-and-so many places from the right-hand end. For the right-hand figures of a number are the least important ones, and in many cases are entirely unknown (especially when the slide rule or a computing machine is used). The mental process for determining the decimal point is as follows:

(*a*) If the multiplier is a number like 3.1416, with only one figure preceding the decimal point, think of this number as "a little over 3"; then the product must be "a little over three times the number which is being multiplied"; and this gives the position of the decimal point at once, by inspection.

(*b*) If the multiplier is a number like 3141.6 [or 0.000 003 141 6], think of this number as "about 3, with the point moved three places to the right" [or "about 3, with the point moved six places to the left"]; then think what the answer would be if the multiplier were simply "about 3," and shift the decimal point accordingly.

Multiplication Tables. Crelle's large volume (G. Reimer, Berlin) gives the product of every three-figure number by every three-figure number; Peters's (G. Reimer, Berlin), of every four-figure number by every two-figure number. The smaller table of H. Zimmerman (Wm. Ernst, Berlin) gives the product of every three-figure number by every two-figure number. Tsuneta Yano's Table (published by the First Mutual Life Ins. Co., Tokyo, Japan) gives the same information as Crelle's Table in small book form.

Division. In long division, where the numbers are given only approximately, the work can be much abbreviated without loss of accuracy by "cutting off" one figure of the divisor at each step, instead of "bringing down" a doubtful zero in the dividend. Thus, $3.1416 \div 2.3026 = 1.3644$.

```
23026)31416(1
      23026
 2303) 8390(3
       6909
  230) 1481(6
       1380
   23)  101(4
         92
    2)    9(4
```

To determine the **position of the decimal point** in a problem of fractional division, shift the point (mentally) in both numerator and denominator (the same number of places in each) until the denominator is a number in the "standard form," that is, a number with only one figure preceding the decimal point. (This will not change the value of the fraction.) Then estimate the approximate magnitude of the quotient by inspection. Thus:

$$\frac{0.2718}{3141.6} = \frac{0.000\ 2718}{3.1416} = \text{"about } 0.000\ 09\text{"} = 0.000\ 08652;$$

$$\frac{31.416}{0.002718} = \frac{31{,}416}{2.718} = \text{"about } 10{,}000\text{"} = 11{,}558.$$

Reciprocals. The reciprocal of N is $1/N$. Instead of dividing by a long number N, it is often better to multiply by the reciprocal of N. The table of reciprocals on pp. 24–27 gives the reciprocal of any number, correct to four figures. Barlow's Table (Spon & Chamberlain, New York) gives the reciprocal of every four-figure number correct to seven figures (but without facilities for interpolation). The reciprocals of numbers having more than four figures are best found by the use of a large table of logarithms.

Reciprocals of $1 \pm x$ when x is Small.

$1/(1+x) = 1 - x + [\text{error} < x^2$, if x is between 0 and 1],
$\quad = 1 - x + x^2 - [\text{error} < x^3$, if x is between 0 and 1].
$1/(1-x) = 1 + x + [\text{error} < x^2 + 2x^3$, if x is between 0 and ½],
$\quad = 1 + x + x^2 + [\text{error} < x^3 + 2x^4$, if x is between 0 and ½].

NOTE. $1/(a \pm b) = (1/a)[1/(1 \pm x)]$, where $x = b/a$.

Notation by Powers of 10. All questions concerning the position of the decimal point are readily answered if each number is expressed in the "standard form," that is, as the product of two factors, one of which is a number with only one figure preceding the decimal point, while the other is a positive or negative power of 10. Thus, 3.1416×10^3 means 3.1416 with the point moved three places to the right, that is, 3141.6. Again, 3.1416×10^{-6} means 3.1416 with the point moved six places to the left, that is, 0.000 003 1416. This notation by powers of 10 should always be used in dealing with very large or very small numbers. Among electrical engineers its use is very general, even for numbers of moderate size.

Square Root. (a) If four figures of the root are sufficient, take the answer directly from the table of square roots, pp. 12–15. (b) To obtain a root of six or seven figures from the table, use the formula: $\sqrt{N} = a + [(N - a^2)/2a]$ (approx.), where a is the nearest value of $\sqrt{N}$ obtainable from the table, with three or four ciphers annexed. Here a^2 must be found exactly, by direct multiplication, so that at least three significant figures of the difference $N - a^2$ shall be known correctly; but this done, the division of $N - a^2$ by $2a$ should be carried to only three figures (logarithms or slide rule may be used).

NOTE. The simplest way to obtain any root of a seven-figure number correct to seven figures is to use a seven-place table of logarithms, if such a table is at hand.

Square Roots of $1 \pm x$ when x is Small.

$(1+x)^{1/2} = 1 + \tfrac{1}{2}x - [\text{error less than } \tfrac{1}{8}x^2 \text{ if } 0 < x < 1]$
$\quad = 1 + \tfrac{1}{2}x - \tfrac{1}{8}x^2 + [\text{error} < \tfrac{1}{16}x^3 \text{ if } 0 < x < 1]$

$(1-x)^{1/2} = 1 - \tfrac{1}{2}x - [\text{error} < \tfrac{1}{8}x^2 + \tfrac{1}{8}x^3 \text{ if } 0 < x < \tfrac{1}{2}]$
$\quad = 1 - \tfrac{1}{2}x - \tfrac{1}{8}x^2 - [\text{error} < \tfrac{1}{16}x^3 + \tfrac{1}{16}x^4 \text{ if } 0 < x < \tfrac{1}{2}]$

NOTE. $\sqrt{a+b} = \sqrt{a}\,(1+x)^{1/2}$, where $x = b/a$.

Cube Root. (a) If four figures of the root are sufficient, take the answer directly from the table of cube roots, pp. 16–21. (b) To obtain a root of six or seven figures from the table, use the formula: $\sqrt[3]{N} = a + [(N - a^3)/3a^2]$ (approx), where a is the nearest value of $\sqrt[3]{N}$ obtainable from the table, with three or four ciphers annexed. Here a^3 must be found correct to seven or eight figures, by direct multiplication, so that at least three significant figures of the difference $N - a^3$ shall be known; but this done, the division of $N - a^3$ by $3a^2$ should be carried to only three or four figures (logarithms or the slide rule may be used).

cover and expands downward. Three screw dowels should be fitted at the top to keep it from working loose. On account of the small space between the liner and the cylinder the liner must be finished on the outside. Figure 16 shows a liner with a flange on the lower end through which tag bolts secure it to the cylinder bottom. At the top is a dovetailed recess into which is calked a ring of soft copper. A modification of this type is shown in Fig. 17 which reduces the volumetric clearance. All these methods allow the liner to expand and contract freely.

Counterbore. To prevent shoulders from being worn in its working surface by the piston rings, the liner or cylinder is counterbored about $\frac{1}{8}$ in. larger in diameter at each end as shown in Figs. 13 and 14, the length of the wearing surface being such that the piston rings will either come flush or overrun a short distance at each end, say 0 to $\frac{1}{8}$ in. at the bottom and $\frac{1}{8}$ to $\frac{3}{8}$ in. at the top. On the other hand the length of the counterbore must be limited so that, when striking clearances of the piston are taken, the piston rings will not entirely overrun and stick on the shoulders.

Table 12

Stroke, in.	Piston clearances, in.	
	Top	Bottom
15–21	$\frac{1}{4}$	$\frac{3}{8}$
22–31	$\frac{1}{4}$	$\frac{1}{2}$
32–41	$\frac{3}{8}$	$\frac{1}{2}$
42–48	$\frac{3}{8}$	$\frac{5}{8}$
49–54	$\frac{1}{2}$	$\frac{5}{8}$
55–66	$\frac{1}{2}$	$\frac{3}{4}$

Piston Clearances. Clearance must be allowed between the piston and the cylinder at each end. This clearance is usually made larger at the bottom than at the top as the wear of the bearings in time will lower the piston. The clearances allowable should be based on the length of stroke rather than on cylinder diameter as the clearance is made the same in all cylinders of the same engine. Clearances should not be less than given in Table 12 unless the pistons and cylinder ends are machined. The cylinder-cover joints will slightly increase the top clearances given.

Cylinder Relief or Safety Valves. Relief valves are provided on top and bottom of all cylinders to prevent fracture of the cylinder parts in case excessive pressure is built up or water hammer occurs. The diameters of relief valves for the different cylinders bear the following relations (to the nearest half inch) to the diameters of the cylinders: high-pressure, 0.10 to 0.115; intermediate-pressure, 0.065 to 0.085; low-pressure 0.045 to 0.06.

Safety valves are usually fitted to the receivers and are the same size as or slightly less than the cylinder relief valve for the corresponding cylinder. Relief and safety valves for high-pressure cylinders are set at 1.10 to 1.15 times the boiler pressure, for intermediate-pressure cylinders at 1.25 to 1.5 times the initial pressures in the cylinders as given in Table 2, and for low-pressure cylinders of triple- and quadruple-expansion engines at about 30 lb.

A cylinder relief valve of the type generally used in shown in Fig. 18. The casing prevents the scalding of attendants by the escaping water, the exit

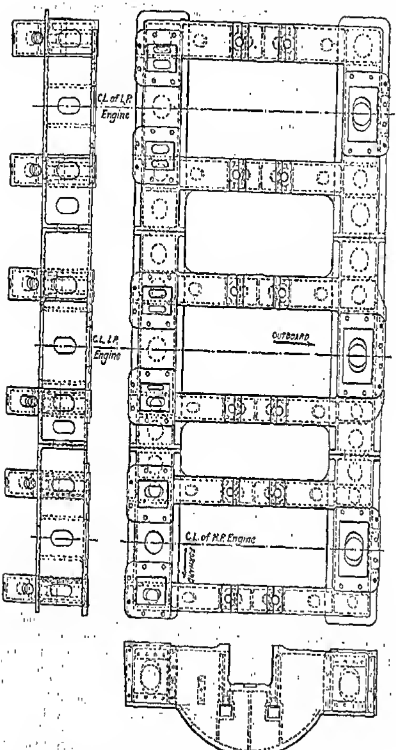

FIG. 28.—Bedplate with dropped bottom.

being on each side near the bottom. If it is desired to reduce volumetric clearance to a minimum, the type of relief valve shown in Fig. 19 should be used. The seat of this valve is fitted in the inner wall of the cover and the exit is through the cored passage (a) to a pocket in the cylinder cover. This pocket is drained by a pipe with its flange on the same level as the relief-valve flange.

Cylinder Drains. Drain cocks or valves are fitted at the lowest point in each cylinder, and valve chest and gear should be provided for operating them from the working platform. The drains are piped to the hot well or condenser. The sizes of cylinder drains, to the nearest quarter inch, for the different cylinders are: high-pressure, 0.04 to 0.055; intermediate-pressure,

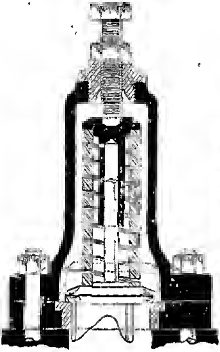

Fig. 18.

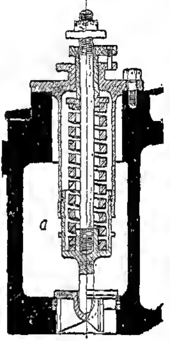

Fig. 19.

Relief valve.

0.03 to 0.04; low-pressure, 0.02 to 0.03 times the diameter of the cylinders. The valve-chest drains are usually made ¼ or ½ in. smaller than the corresponding cylinder drains.

By-pass Valves. For admitting live steam to the intermediate-pressure or low-pressure cylinders for starting the ending easily or for starting the engine in case the high-pressure crank should be on its dead center, by-pass valves are fitted. Steam is taken from the main steam pipe or from the inlet side of the throttle valve. Two-inch to 3-in. valves are used for engines of 1,000 to 3,000 ihp, and 3- to 4-in. for larger engines.

Indicator connections of ¾ or 1 in. for indicator pipes are provided at each end of the cylinder, care being taken that the connections are not near the cylinder ports so that the inrushing steam during admission will

exceed 1,200 lb. The **over-all dimensions** of bedplates and the distance of the side girders and bottom from the center of the shaft, to ensure sufficient clearance from the path of the connecting rod, are determined when laying down the engine. The **depth of the side girders** is from 1.5 to 2 and the width from 1.25 to 1.6 times the diameter of the shaft. The **width of the cross girders** is 2 to 4 in. less than the lengths of the main bearings which they carry. The **thickness of metal in bedplates** for an 8-in. crankshaft is about 1 in. on top and bottom and $\frac{3}{4}$ in. on the sides. For an 18-in. shaft the corresponding figures are $1\frac{1}{2}$ and $1\frac{1}{4}$ in. The **thickness of flanges** for the holding-down bolts should be 1.4 to 1.8 times the thickness of the

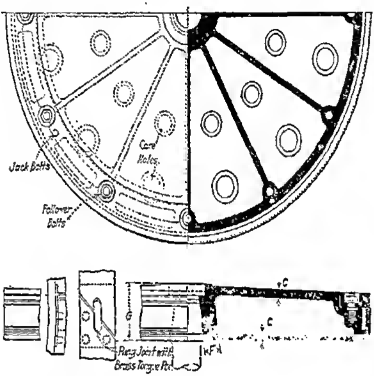

FIG. 29.—Cast-iron piston.

adjoining metal and the width about 2.75 times the diameter of the bolt. **To facilitate casting and handling,** bedplates are often made in two or more sections bolted together. If the main condenser is built in as part of the engine framing, it may rest on top of the bedplate or extend to the foundation, in which case the bedplate is bolted to it. Bedplates are secured to the foundations by bolts passing through cast-iron or steel liners of thickness to suit the alignment. The **size and number of holding-down bolts** must be sufficient to keep the engine in alignment when the vessel is rolling. The diameters run from $1\frac{1}{8}$ in. for a 1,500- to $1\frac{1}{2}$ in. for a 7,500 ihp engine; pitched 8 or 9 diameters. A certain number should be fitted bolts or all of them should be a close fit. Sometimes cast-steel chocks, riveted to the structural foundation, are fitted at each corner of the bedplate in lieu of fitted bolts.

not affect the pressure recorded by the indicator. The three-way cock to which the indicator is connected should be located near the middle of the cylinder. Valves should be fitted close to the cylinder at top and bottom so the pipes can be closed off when the indicators are not in use.

Lagging. All cylinders and valve chests are lagged all over with 1½- to 2-in. magnesia block or plaster and covered over with galvanized or planished steel secured to the lagging flanges by screws.

Stuffing Boxes. The piston-rod stuffing box is usually a separate casting bolted to bottom of cylinder (Figs. 13 and 14). The opening thus provided permits the use of a heavy bar in boring the cylinder. The stuffing box should be designed to accommodate any of the standard makes of metallic packing to allow change in the type of packing. The **diameter of**

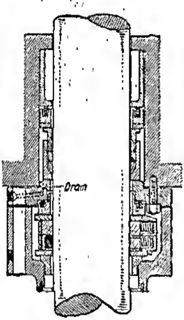

Fig. 20.

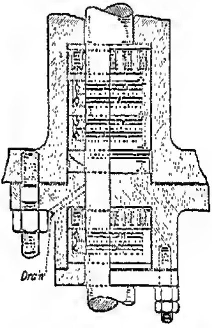

Fig. 21.

Types of metallic packing.

stuffing box for metallic packing is approximately diameter of rod plus 2 in. for 4-in. rods to diameter plus 3 in. for 9-in. rods. The **depth of box** varies with the design of packing. The space required for soft packing is about the same as for metallic. The **stuffing box for a piston-valve** stem is usually cast with the bottom valve chest cover (Fig. 13) and **for a slide-valve** stem with the valve-chest bottom (Fig. 14).

Metallic Packing. There are many types in use but all are essentially the same in principle, consisting of one or more systems of ring segments held securely against the rod by pressure induced by axial, radial, or circumferential springs. Figure 20 illustrates a typical example of double metallic packing used **for high pressure.** White metal packing rings of the inner set are held against the moving rod by axial springs and conical seatings in a retaining cup, and those for the outer set by a combination of radial and axial springs without the use of the conical seating. **For lower pressure,** the outer set is often made a duplicate of the inner set. Figure 21 is a **double packing** in

Reciprocating Parts

Pistons may be of **cast iron of box section** (Fig. 29) or of **cast steel conical in form** (Fig. 30). Either form combines lightness and strength. As the relative weights of the different pistons greatly affect the balance of the engine, the high-pressure piston is often made of cast iron almost or entirely solid, and the low-pressure piston of cast steel as light as consistent with the necessary strength. The curves in Figs. 31 and 32 give **proportions of cast-iron and cast-steel pistons.** If the high-pressure piston is of cast

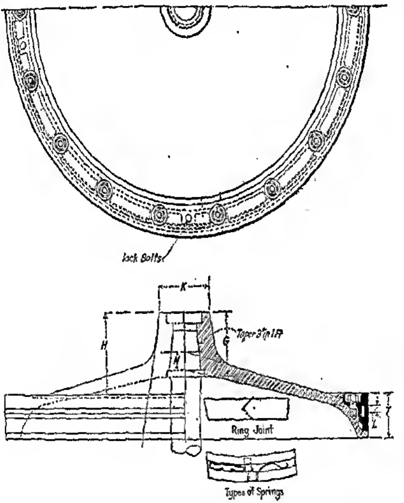

Fig. 30.—Cast-steel piston.

steel, it should be much thicker than indicated by the curves to increase the weight. It is usual to make the depth of face and depth of hub the same for all cylinders. In hollow cast-iron pistons the top, bottom, and ribs are generally made the same thickness, and the number of follower or junk ring-bolts corresponds to the number of ribs. For solid cast-iron and for cast-steel pistons the pitch of the bolts in diameters is 6 for high-pressure, 9 for intermediate pressure, and 12 for low-pressure pistons. Bolts and nuts must be securely locked against backing out and should not project above the follower face. To prevent bolts from rusting fast in the piston, brass plugs are some-

which the elements of the inner and outer sets are interchangeable. The packing rings are held against the moving rod by axial and circumferential springs. When double metallic packing is used, the chamber for holding the outer set is a separate casting bolted on the outside of the stuffing box. For high-pressure cylinders using **superheated steam** or saturated steam above 190 lb, the packing rings must be of a special composition.

A drain must always be fitted to take off the leakage or condensation which would otherwise cause an objectionable drip from the stuffing box; these drains are piped to the condenser, except the low-pressure piston rod drain which is generally carried into the low-pressure receiver to prevent air being drawn into the condenser. A separator or collector is sometimes fitted to prevent cylinder oil from being drawn into the condenser. A commercial brand of soft packing is sometimes used for the low-pressure piston rods and valve stems. When metallic packing is used **in a new engine**, it is very important that the steam ports and passages be thoroughly cleaned, preferably by pickling; otherwise sand and grit will enter the stuffing boxes and wear the packing. Sometimes the stuffing boxes are filled with soft packing until the grit has all worked out and then the metallic packing is installed. In **designing stuffing boxes** for metallic packing, it is advisable to prepare tentative sketches, giving fixed dimensions and limits, and to submit these to packing manufacturers for recommendations and criticisms in order to use a standard size. For **materials for metallic packings**, see p. 898.

Main Steam, Receiver, and Exhaust Pipes and Passages. Steam velocities are based on piston displacement. Velocity in fpm = area of cylinder × piston speed ÷ area of pipe or passage; piston speed is in feet per minute and areas in sq in. To avoid drop in pressure the areas of pipes and passages should be such that velocities will not exceed those given in Table 13 but velocities should be kept lower if possible.

Table 13. Velocities of Steam in Pipes and Passages

	H-p	First I-p	Second I-p	L-p
Main steam pipe	5,500			
Steam to first i-p cylinder	.....	6,500		
Steam to second i-p cylinder	....	. .	7,500	
Steam to l-p cylinder	....	.....	.....	8,500
Exhaust to condenser	. . .	.	. . .	6,000
Steam through valve liner at maximum port opening	5,000	6,500	8,000	9,000
Steam or exhaust through ports of cylinder	5,000	6,500	7,500	8,500
Exhaust through total area of valve liner	4,000	5,000	6,500	8,000

On account of the increased **resistance through the throttle valve** it should be ½ to 1 in. larger in diameter than the main steam pipe. **Velocities through cylinder ports** should be fairly high to reduce condensation and permit of small clearance volumes, but the **exhaust through the valve liners** should be low on account of the increased resistance. Instead of receiver pipes the exhaust from one cylinder is often led to the next through a passage cast with the cylinders. For long receiver pipes expansion joints must be fitted unless expansion can be taken care of by pipe bends (see p. 942). The exhaust pipe from the low-pressure cylinder to the condenser should be of ample area and as short and direct as possible as it is important that excessive

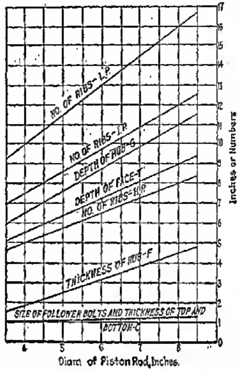

Fig. 31.—Proportions of cast-iron pistons (letters refer to Fig. 29).

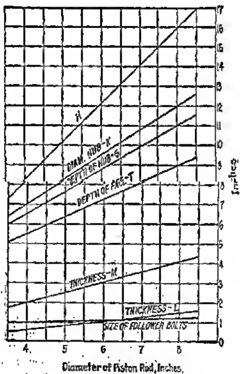

Fig. 32.—Proportions of cast-steel pistons (letters refer to Fig. 30).

back pressure be avoided. Receiver and exhaust pipes may be cast iron, steel, or copper.

Cylinder covers in merchant vessels are of cast iron with a **single wall** with deep radial ribs on the outside unless it is desired to use steam jackets in which case **double walls** are used. Double walls may also be used for covers of very large cylinders. As it is difficult to calculate the stresses in

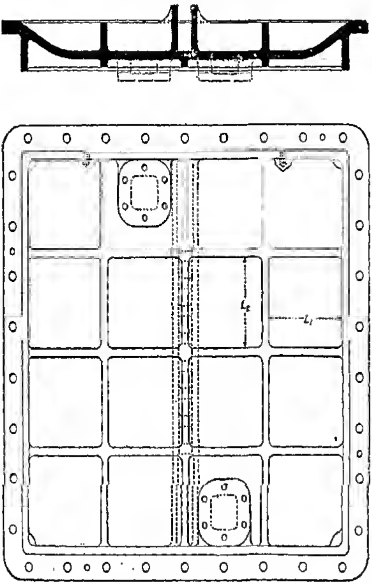

Fig. 22.—Slide-valve chest cover.

cylinder covers, it is usual to proportion them from successful practice. **Thickness of metal in cover** is about 0.85t for small cylinders and t for large cylinders, where t is the thickness of cylinder without liner. The **ribs** are the same thickness or sometimes slightly heavier. Cylinder covers are conical to follow the shape of the piston and to obtain greater strength. They should be well ribbed to avoid too large flat surfaces between ribs. The width of the steam joint is about 2.8 $\times$ d and the thickness of bolting

times fitted in the piston into which the bolts are screwed. Piston castings up to 35 in. diameter should be turned about $\frac{1}{32}$ in. less than the diameter of the cylinder bore and larger pistons about $\frac{1}{16}$ in. The top and bottom walls of a cast-iron piston must be of sufficient strength to withstand the shock due to water collecting in the cylinder. The strength of a cast-steel piston should be calculated by considering half the piston as a cantilever loaded at the center of pressure and breaking through the center line. The cross section is divided into a number of triangles or rectangles as shown in Fig. 33 and the section modulus found by the method on p. 1071. Stress $= \frac{P \times A \times r}{2 \times 2 \times Z}$ in which P is pressure per sq in., A is total area of piston in sq. in., r is radius to center of pressure $= 0.424 \times$ radius of piston, and Z is modulus of half section. Stress figured by this method should not exceed 3,000 psi. It is usual to use a pressure of 30 lb in the calculation for low-pressure pistons.

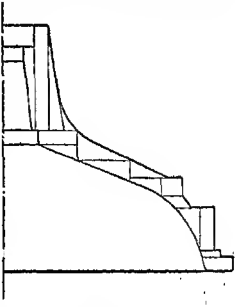

FIG. 33.

Piston Rings. No parts of the reciprocating engine require more care in their design than the piston rings, the function of which is to prevent leakage

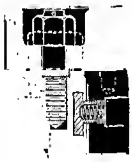

FIG. 34.

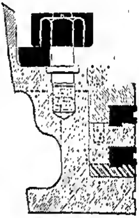

FIG. 35.

Types of Piston packing.

of steam past the piston by exerting a uniform pressure all around without excessive friction. To accomplish this was a relatively simple matter when low-pressure wet steam was used, but with high-pressure and superheated steam the duties of the piston rings, especially for high-pressure cylinders, have become much more exacting. The unequal expansion of the piston and

flange about 1.35 $\times d$ where d is diameter of the studs. In large cylinders a **manhole** is fitted in the cover (Fig. 14) so that the piston and cylinder may be examined without lifting the cover. A **false cover** of cast iron or checkered steel plate is fitted on top of the ribs and the space between ribs is filled with magnesia. If a **tail rod** is used, the cylinder cover is fitted with a stuffing box or a closed cast-iron casing in which the tail rod works.

Valve-chest covers for piston-valve chests are of the same construction as cylinder covers. They contain the balance piston cylinder, when fitted, as shown in Fig. 14. Valve-chest covers for slide valves are rectangular in shape and on account of the large area must be heavily ribbed as shown in Fig. 22. The **width of the steam joint** should be about 2.6 $\times d$ and the **thickness of the bolting flange** about 1.25 $\times d$ where d is the diameter of the studs. The **thickness of metal in cover** is usually the same as the cylinder walls. Slide valves are used only on cylinders where the pressure is low and therefore the design of this cover is not so difficult as if it carried full-pressure steam.

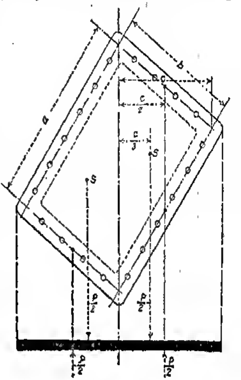

Fig. 23.

It is well however to calculate the **stress in the cover** by the following method given by Bauer: Experiments have shown that square or rectangular plates, when subjected to a uniform strain under hydraulic pressure, split across the diagonal and should therefore be calculated for a bending stress along that line. Load on cover (see Fig. 23), $P = a \times b \times p$ where p is test pressure psi and a and b are dimensions of cover to center line of bolts. Half of the load may be considered as acting at the center of gravity S of half the cover; then the bending moment about the diagonal is $\frac{P}{2} \times \frac{c}{3}$. This load is counteracted by the resultant of two forces which act along the sides a and b. Then the moment about the diagonal $= M_b = \frac{P}{2} \times \frac{c}{2} - \frac{P}{2} \times \frac{c}{3} = \frac{Pc}{12}$. Expressing c in terms of a and b and $P = a \times b \times p$, then $M_b = \frac{pa^2b^2}{12a^2 + b^2}$. Stress $= \frac{Mb}{Z}$ where Z is modulus of the diagonal section found by the method given on p. 1071. Stresses calculated by this method

the cylinder walls and the necessity of providing for wear render some means of adjustment necessary.

Ordinary **concentric rings** of square or rectangular section, cut and sprung into position, do not exert a uniform pressure but bear much harder near the ends. This has a tendency to wear the cylinder bore oval. To overcome this and at the same time to improve the steam joint by making the pressure of the rings uniform all around the cylinder wall, springs are often fitted behind the rings as shown in Figs. 30 and 34. Rings of this type should not be used as **floating snap rings** unless they are restrained by clamping of the follower or by **nonelastic bull rings,** which do not bear against the cylinder walls (Figs. 30, 35 to 37). Holes are tapped into the bull ring so that it may be removed with the rings without drawing the piston.

Eccentric or **ramsbottom rings,** thicker in the middle than at the ends, must be used for all snap rings. To prevent steam leaking past them, the rings are usually dowelled together so that the joints will come on diametrically opposite sides of the piston. In addition a brass tongue piece is some-

FIG. 36.

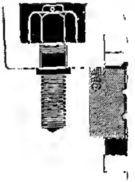

FIG. 37.

Types of piston packing.

times fitted as shown in Fig. 29. Piston rings are always made of hard cast iron to resist wear. Figure 37 shows a very satisfactory type of piston packing for high pressures in which the rings are so fitted that when the follower bolts are loosened the rings will expand and fill the cylinder bore and when the bolts are tightened the rings will be pinched in position. This arrangement gives the effect of an accurately fitted solid piston with provision for adjustment. Figures 35 and 36 show other satisfactory types of high-pressure packing rings. In these the rings float, but the amount is limited by shoulders on the bearing rings. Figures 30 and 34 show satisfactory types of intermediate-pressure and low-pressure piston rings, and Fig. 29 a very satisfactory low-pressure packing ring. There are a number of patented piston packings of various designs in use.

Piston Rods. The **length** is found when laying down the engine and is usually about $1\frac{1}{2}$ times the stroke. The rods for all cylinders are made **interchangeable,** if possible. The **diameter** is determined from the unbalanced load, P, treating the rod as a column with round ends. The stress in the body of the rod $= P \div$ area and is usually about 2,000 psi. The

may safely run as high as 6,000 psi. If a guide for the slide valve is cast with the cover and is a strength member, it should be considered in calculating the section modulus. The pressure is considered as acting to the center line of the bolts.

Strength of Flat Plates. In designing cylinders and cylinder and valve chest covers it is often necessary to calculate the strength of flat sections of metal between ribs. A number of formulas for flat plates have been published, but rarely is the same formula satisfactory for both thick and thin plates. In cylinder parts the flat plates are fixed around the edges and uniformly loaded, and it is usual to calculate them for the test rather than for the working pressure. Probably the simplest and most satisfactory method of figuring flat plates is by equating deflections, although the strength of a flat plate can be determined only approximately. If the plate to be figured is not rectangular, an equivalent rectangle should be assumed. Total load, W = pressure per sq in. $\times$ area. Part of the total load, W_1, is carried by the edge L_2 (Fig. 22) and part of the load, W_2, is carried by the edge L_1. Equating the deflections at the middle of the rectangular plate $(W_1 \div W_2) = (L_2^4 \div L_1^4)$. Therefore $W_1 = WL_2^4 \div (L_1^4 + L_2^4)$ and $W_2 = WL_1^4 \div (L_2^4 + L_1^4)$. Stress due to $W_1 = \dfrac{6W_1L_1}{12L_2t^2}$ and stress due to $W_2 = \dfrac{6W_2L_2}{12L_1t^2}$, where t is thickness. Stress figured by this method should not exceed 2,000 psi for cast iron, based on test pressure, but it will usually be much less than this.

Framing and Beds

Framing of merchant engines usually consists of cast-iron housings of box section either straight or inverted Y (Fig. 24). In small engines, and in larger engines where it is desired to keep the front of the engine open, forged-steel front columns are used with straight or **Y-box housings** carrying the crosshead guides in the back. In engines of intermediate and large sizes **straight box housings** are generally used in front and Y-housings in the back, each housing carrying a crosshead guide. In very large engines four cast-iron or cast-steel housings may be used for each cylinder each carrying a guide. In **naval and yacht engines**, where saving of weight is important, the framing is made up of **forged-steel columns** and braces. Housings are subjected to direct tensile and compressive stress from the unbalanced load, to direct compressive stress from the weight of the cylinders, which may be greatly augmented by rolling of the vessel, and to bending stress from the crosshead pressure on the guides. As the stresses are always low, housings must be proportioned for rigidity rather than strength to avoid deflection. The bending stress from the crosshead is ordinarily only about 200 psi and need not be computed. The direct stress at the top of the housing from the unbalanced load and the weight of the cylinders should not exceed 800 psi. The **thickness of metal in housings** is about 1 in. for a 20-in. and $1\frac{3}{8}$ in. for a 35-in. cylinder. Back housings should have one-fifth to one-third more sectional area than front housings. The thickness of the metal should be increased at top and bottom to provide better attachment for the flanges. The **thickness of flanges** is about 1.4 times the diameter of the bolts. **Number and diameter of bolts** securing the housings to the cylinders and bedplates are determined from the unbalanced load, P. Stresses should be kept low to ensure rigidity, about 2,400 lb for the upper and 1,800 lb for the lower bolts being good practice. Diameters average about $1\frac{1}{2}$ in. for engines

factor of safety, which is usually about 20, is found by dividing the destructive load per square inch, from Pencoyd's tables given on p. 1070, by the stress in the rod. These destructive loads are based on $L \div \rho$, where L is the length of the column and ρ, the least radius of gyration, both in inches. $\rho = D \div 4$ for solid rods and $\sqrt{D^2 + d^2} \div 4$ for hollow rods in which D is diameter of rod and d is diameter of hole. The stresses are kept low and the factors of safety high, to permit turning down if the rods should be scored by the

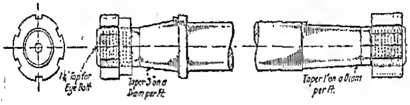

FIG. 38.—Piston rod.

metallic packing. The piston rod is tapered about 3 in. per ft on diameter in the piston and 1 in. in the crosshead (Fig. 38). The large taper facilitates the removal of the piston. A collar at the end of the taper against which the piston rests prevents this large taper from splitting the piston. The **diameter of the thread** at each end is about 0.7 to 0.8 times the diameter of the rod and is proportioned from the unbalanced load, P, for a stress of 3,500 to 4,000 lb. Four threads per inch are generally used for all sizes. The **diameter of tail rod,** if fitted, is about 0.7 times the diameter of the piston rod, or as large as the threads of the piston-rod nut will permit.

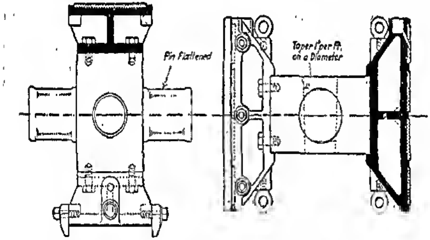

FIG. 39.—Central-block type of crosshead.

Crossheads. In merchant engines the **central-block type** of crosshead with two pins is generally used (Fig. 39). The **depth of the central block** is 1.6 to 1.8 and the **length** 1.5 to 1.8 times the diameter of the piston rod. The **width,** when one slipper is used, is about the same as the depth; with two slippers it is made much wider to keep the slippers clear of the connecting rod. The central block should be figured for strength as a beam supported at the middle of the pins and loaded by the unbalanced load on the piston rod P. Stress $= PL \div 4R$ where L is length between middle of pins and R is resistance of the section $= bd^2 \div 6$; b is width less the average width of the

with a 20-in. and $2\frac{1}{4}$ in. for a 35-in. high-pressure cylinder, the lower bolts usually being made somewhat larger than the upper. Forged-steel front columns are proportioned from the unbalanced load, P, considering them as columns fixed at the ends by the method given under piston rods (p. 1092). The full unbalanced load, P, should be used with a factor of safety of about 25 to allow for the weight of the cylinders and the increased load due to rolling of the vessel. If the main condenser is built in as a part of the engine framing, the back housings rest on top of the condenser.

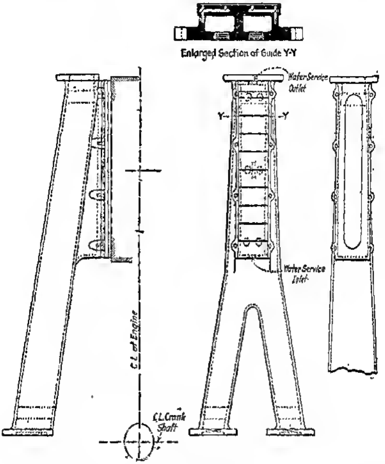

Fig. 24.—Cast-iron housings.

Crosshead Guides. Small engines usually have guides of the bar type (Fig. 25). This type is favored for tugboat and other engines which do a lot of backing as the surface is the same for backing as for going ahead. The guide is generally cast iron of box section for water circulation, but when used on engines with a stroke as long as 42 in. cast or forged steel should be used to ensure rigidity. The strength of the bar should be computed as a beam supported at the ends and loaded in the middle by the load on the crosshead slippers, P_2 (see Fig. 44). Stress for cast iron should not exceed 2,750 psi. Engines of small and intermediate size often have guides of the single type (Fig. 26). The ahead guide, which is hollow for water circulation, is

hole for the piston rod and d is depth. Stress may safely run as high as 3,000 lb. The **single-pin type** of crosshead, which usually consists of a bearing box on the end of the piston rod, is also used (Fig. 40). In this type the pin is shrunk into the fork of the connecting rod. Stresses in the bolts

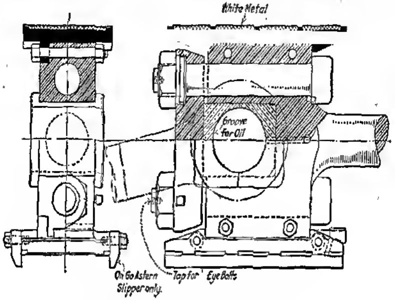

Fig. 40.—Single-pin type of crosshead.

and caps, due to the unbalanced load P, should be calculated as shown on p. 1100. The same stresses are allowable.

Crosshead Pins. As the crosshead-pin bearings are oscillating instead of rotating bearings, higher pressures per inch are allowable than on the crankshaft and crankpin bearings. The pressure is produced by the load on the

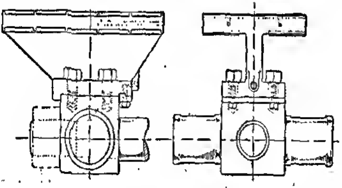

Fig. 41.

connecting rod P_1 (see Fig. 44), and pressures of 500 to 600 psi are allowable. The pins must be proportioned for strength as well as area. The **diameter of the pins** of the type shown in Fig. 39 is 1.1 to 1.2 times the diam of the piston rod and the length 1.1 to 1.25 times their diam. The pin is figured as a cantilever loaded at the middle of its length by one-half the load on the connecting rod, P_1. Stress $= P_1l \div 2 \times 2R$ where l is length of pin and

bolted to the back housing, the same bolts also securing the backing guides. The load on these bolts $= \frac{P_1(a + b)}{2}$ in which a and b are as shown in Fig. 26.

Intermediate and large engines usually have **guides on both front and back housings.** The guides are usually separate castings, cored for water circulation and bolted to the housings (Fig. 24). Very large engines with four housings to each cylinder have a guide on each housing. The **surface of the guides** is proportioned to suit the area of the crosshead slippers, and the **length** is such that the slippers overrun about 1 in. at each end to prevent wearing of shoulders. The bar and single-slipper types of guides require no adjustment to allow for expansion of the cylinder; this is required with guides on both housings, the adjustment being made in the latter type, to prevent crossheads from pounding after the engine has been running for some time. The working surfaces of the guides are not lined with white metal but usually have grooves to retain the oil.

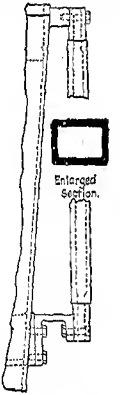

Fig. 25.

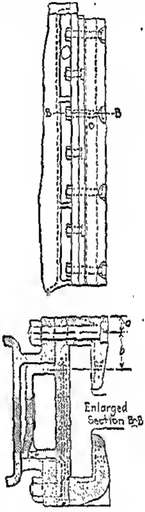

Fig. 26.

Types of crosshead guides.

Bedplates for merchant engines are cast iron of box section with either flat or dropped bottom as shown in Figs. 27 and 28. The **dropped-bottom type** is preferable as the housings are shorter and the shaft lower while ample space is allowed for building rigid foundation girders under the bed-

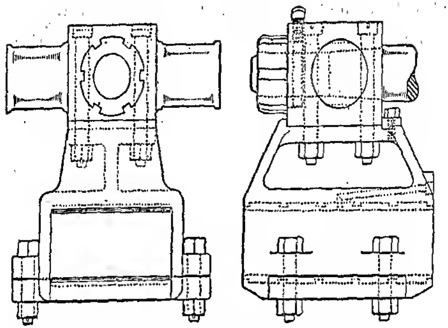

FIG. 42.

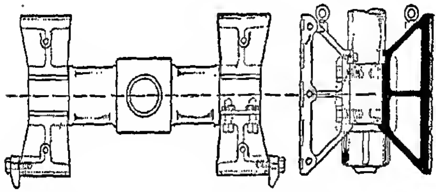

FIG. 43.

R is resistance to bending $= d^3 \div 10.2$. Crosshead pins are flattened on the sides to facilitate the distribution of oil from top to bottom.

In the single-pin type (Fig. 40) diameter of the pin is 1.2 *to 1.5 times the diameter of the piston rod and the length* about 1.4 to 1.6 times its diameter. The pin is figured as a beam fixed at the ends and loaded at the middle of its length by the load on the connecting rod, P_1. Stress $= P_1l \div 8 \times R$, where l is length of pin and R is resistance to bending $= d^3 \div 10.2$. Stresses in pins of either type may safely run as high as 3,500 psi.

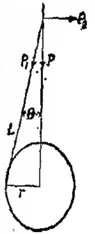

FIG. 44.

Crosshead Slippers. *Crossheads with two slippers* (Fig. 39) are generally used in intermediate and large engines. For smaller engines one slipper of the type shown in Fig. 41 or the box type (Fig. 42) are used. For very large engines with four housings to each cylinder four slippers are used (Fig. 43). *Slippers are usually of cast iron but some-* times of cast steel and lined with white metal. When one

plates. Bedplates are proportioned for mass and rigidity rather than for strength, but it is usual to calculate the stress in the cross girders as beams

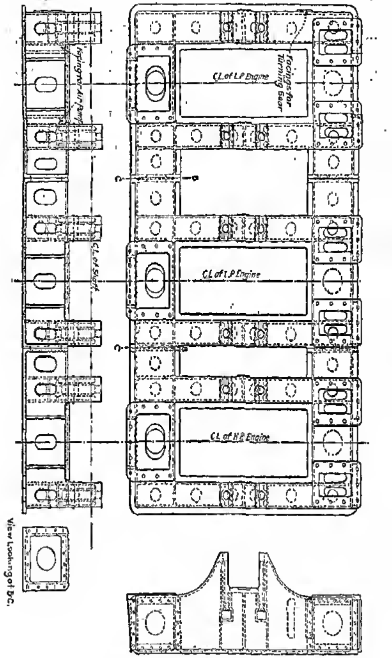

FIG. 27.—Bedplate with flat bottom.

supported at the middle of the side girders and loaded in the middle by the unbalanced load, P. Stress $= Pl \div 2 \times 4R$ where R is the modulus of section found by the method on p. 1071. To ensure rigidity, stress should not

slipper is used, the bolts securing the slipper to the central block must be proportioned to carry the load when backing. When two or four slippers are used the ahead or astern slippers must be fitted with gibs on each side as

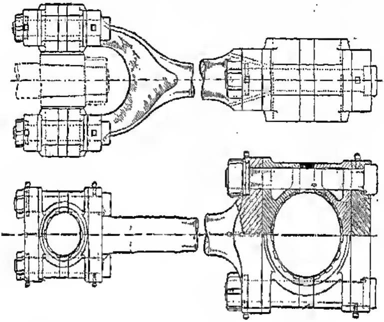

Fig. 46.

Connecting rods.

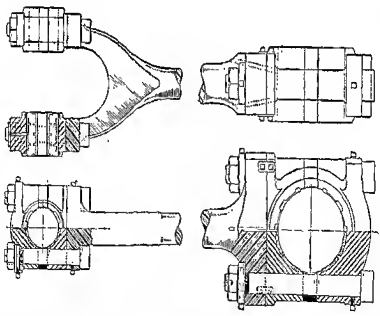

Fig. 45.

shown in Figs. 39, 40, and 43 to keep the crosshead in alignment. To facilitate the removal of the slippers keys are fitted in the upper side of the central block as shown in Figs. 41 to 43.

NOTE. The simplest way to obtain any root of a seven-figure number correct to seven figures is to use a seven-place table of logarithms, if such a table is at hand.

Cube Roots of $1 \pm x$ when x is Small.

$$(1+x)^{1/3} = 1 + \tfrac{1}{3}x - [\text{error} < \tfrac{1}{9}x^2 \text{ if } 0 < x < 1].$$
$$= 1 + \tfrac{1}{3}x - \tfrac{1}{9}x^2 + [\text{error} < \tfrac{1}{16}x^3 \text{ if } 0 < x < 1]$$
$$(1-x)^{1/3} = 1 - \tfrac{1}{3}x - [\text{error} < \tfrac{1}{9}x^2 + \tfrac{1}{10}x^3 \text{ if } 0 < x < \tfrac{1}{2}]$$
$$= 1 - \tfrac{1}{3}x - \tfrac{1}{9}x^2 - [\text{error} < \tfrac{1}{16}x^3 + \tfrac{1}{16}x^4 \text{ if } 0 < x < \tfrac{1}{2}]$$

NOTE. $\sqrt[3]{a+b} = \sqrt[3]{a}(1+x)^{1/3}$, where $x = b/a$.

LOGARITHMS

Tables of Logarithms. The use of a table of logarithms greatly reduces the labor of multiplication, division, raising to powers, and extracting roots. The table on pp. 42–43 is carried out to four significant figures, and the following explanations should be sufficient to permit the use of the table readily, even by one without previous experience. For algebraic theory, see p. 113.

If more than four-figure accuracy is required, recourse must be had to a larger table. Five-place tables are available in great variety; the Macmillan Tables, 1913 or Albrecht, "Logarithmisch-Trigonometrische Tafeln," are perhaps as convenient as any. If more than five figures are required, use Bremiker's six-place table, or proceed at once to a seven-place table: Schrön (Vieweg & Sohn, Braunschweig); Bruhns; Vega-Bremiker. If extreme accuracy is required, use the eight-place table by Bauschinger and Peters (Engelmann, Leipzig). Logarithmic paper, see p. 170.

To Find the Logarithm of Any Given (Positive) Number.

(*a*) WHEN THE GIVEN NUMBER IS BETWEEN 1 AND 10.

An inspection of the table on pp. 42–43 shows that as the number increases from 1 to 9.99. . . the logarithm of that number increases continuously from 0 to 0.999. . . For example, log 2.97 = 0.4728; log 2.98 = 0.4742.

If the given number contains four significant figures, it is necessary to interpolate between the tabulated values, as follows:

To find log 2.973, notice that this number is 3/10 of the way from 2.97 to 2.98; hence its logarithm will be (approximately) 3/10 of the way from 0.4728 to 0.4742. The difference here is 14 units, and 3/10 of this difference is 4 (to the nearest unit); hence, by adding this 4 to 4728, log 2.973 = 0.4732. This process of interpolating should be performed mentally; the step of finding the tabular difference will be facilitated by a glance at the last column on the right, which gives, for each line of the table, the average of the differences along that line.

Again, to find log 4.098: From table, log 4.09 = 0.6117; adding 8/10 of the difference (11), or about 9, gives: log 4.098 = 0.6126. Or better, since 8/10 of the way forward is equal to 2/10 of the way back, find in table log 4.10 = 0.6128, and *subtract* 2/10 of 11, or 2, giving log 4.098 = 0.6126. It should be noted that any interpolated value may be in error by 1 in the last place.

If the given number contains more than four significant figures, it should be cut down to four figures (see p. 88), since the later figures will not affect the result in four-place computations.

(*b*) WHEN THE GIVEN NUMBER IS LESS THAN 1 OR MORE THAN 10, it is simply necessary to notice that every such number can be regarded as obtainable from some number between 1 and 10 by merely shifting the decimal point (see p. 90); and that according to the rule at the foot of the table, moving the decimal point n places to the right [or left] in the number-column is equivalent to adding n [or $-n$] to the logarithm in the body of the table.

For example, to find log 2973. Here $2973 = 2.973 \times 10^3$ (*i.e.*, 2.973 with the decimal point moved 3 places to the right). From the table, log 2.973 = 0.4732. Hence, log 2973 = 0.4732 + 3, which may be written as 3.4732.

Again, to find log 0.0002973. Here $0.0002973 = 2.973 \times 10^{-4}$ (*i.e.*, 2.973 with the decimal point moved 4 places to the left). From the table, log 2.973 = 0.4732. Hence, log 0.0002973 = 0.4732 − 4. (This may be written as $\bar{4}.4732$, if desired, and is equal of course, to − 3.5268; this latter form, however, is not convenient in practice.)

It is thus evident that the logarithm of every positive number may be regarded as consisting of two parts: a decimal fraction, which is always positive (or zero); and a whole number, which may be positive, negative, or zero. The fractional part is called the **mantissa**, and is found from the table; the whole-number part is called the **characteristic**, and is determined by inspection.

To Find the Number Corresponding to a Given Logarithm.

(*a*) When the given logarithm is a positive decimal fraction (characteristic zero), simply reverse the process for finding the logarithm of a number between 1 and 10.

For example, given log $N = 0.4732$; to find N. In the body of the table it is seen that 0.4732 lies a little beyond 0.4728; hence N must lie a little beyond 2.97. By taking differences it is found that 4728 is in fact $\frac{4}{14}$ of the way from 0.4728 to the next higher logarithm; therefore N must be $\frac{4}{14}$ of the way from 2.97 to the next higher number. But $\frac{4}{14}$ of 1 is 0.3 (to the nearest tenth), hence $N = 2.973$.

Again, given log $N = 0.6126$; to find N. Here, 0.6126 is $\frac{9}{11}$ of the way from 0.6117 to the next higher logarithm; therefore N must be $\frac{9}{11}$ of the way from 4.09 to the next higher number. But $\frac{9}{11}$ of 1 is 0.8 (to the nearest tenth), hence $N = 4.098$.

(*b*) When the given logarithm has any given value (characteristic not zero), proceed as follows: First, be sure the given logarithm is in the "standard form," that is, a positive decimal fraction (mantissa) plus a positive or negative whole number (characteristic). For example, if log N is originally given in the form log $N = -3.5268$, this must first be reduced to the (equivalent) form log $N = 0.4732 - 4$ (or $\bar{4}.4732$), before entering the table. Having the logarithm given in the standard form, suppose for the moment that the characteristic is zero, and find in the table the number corresponding to the given mantissa; then move the decimal point to the right or left according as the value of the characteristic is positive or negative.

For example, given log $N = 0.4732 + 3$; to find N. From the table, the number corresponding to 0.4732 is 2.973. The characteristic (+ 3) directs that the decimal point be moved 3 places to the right; hence $N = 2.973 \times 10^3 = 2973$.

Again, given log $N = 0.4732 - 4$; to find N. From the table, the number corresponding to 0.4732 is 2.973. The characteristic (− 4) indicates that the decimal point is to be moved 4 places to the left; hence $N = 2.973 \times 10^{-4} = 0.0002973$.

The number corresponding to a given logarithm is called its **antilogarithm**. Thus, if log 2973 = 0.4732 + 3, then 2973 = antilog (0.4732 + 3).

Note 1. In most tables of logarithms the decimal point is omitted, the tables being in fact not tables of logarithms, but tables of mantissas. This omission is of no consequence to the experienced computer but is often perplexing to one who makes only occasional use of such tables.

Note 2. Many computers prefer to write negative characteristics in the form of some positive number minus some multiple of 10; thus, 0.4732 − 4 = 6.4732 − 10; 0.4732 − 13 = 7.4732 − 20; etc.

Fundamental Properties of Logarithms. The usefulness of logarithms in computation depends on the following properties:

$$(1)\ \log (ab) = \log a + \log b; \quad (3)\ \log (a^n) = n \log a;$$
$$(2)\ \log (a/b) = \log a - \log b; \quad (4)\ \log \sqrt[n]{a} = (1/n) \log a;$$
$$(5)\ \log 10^n = n$$

It is to be noted also that log 1 = 0, log 10 = 1, and log $(1/n) = -\log n$.

The pressure of the slipper on the guide, P_2, is the component of the load on the connecting rod, P_1, perpendicular to the guide as shown in Fig. 44; $P_2 = P_1 \sin\theta$ or $P \tan\theta$. The surface of the slipper should be proportioned for a pressure of about 40 psi. When single slippers of the type shown in Fig. 41 are used the backing surface is 65 to 75 percent of the ahead surface.

Connecting Rods. The usual type used in merchant engines is shown in Fig. 45. The crank-end and crosshead-end boxes and caps are lined with white metal and are usually of cast steel, although sometimes of brass. Caps are generally cast in one piece, but cast-iron or brass boxes and forged-steel binders are sometimes used as shown in Fig. 46. Setscrews are fitted in the crankpin cap and in the upper end of the connecting rod to keep the bolts from falling out when the nuts are removed, enabling caps and bolts to be handled together. For intermediate and large engines there should be two oil holes to the crankpin with pipes led to the oil boxes on top of the crosshead-pin bearings. If the single-pin type of crosshead is used, the fork of the connecting rod is made with solid eyes and the pin shrunk in. The length between centers of connecting rods for main engines, is usually 2.25 times the stroke, but this ratio is often made 2.5 for small engines and 2 for large engines. The diameter at the upper end is 0.90 to 0.95 times the diameter of the piston rod, and the diameter at the lower end about 1.25 times the diameter of the upper end. The rod must always be figured for strength as a column with hinged ends. This is done by the method explained on p. 1092, except that the load is taken as $P_1 = P \sec.\ \theta$, where P is the unbalanced load and θ the angle whose sine is equal to the crank radius ÷ length of rod (Fig. 44). In figuring the factor of safety the stress and radius of gyration must be taken at the middle of the rod. The factor of safety is usually about 20. The method of figuring bolts and caps is the same as explained on p. 1101, except that P_1 is used instead of P. The same stresses are allowable. The thickness over flats at the fork end is about ½ in. more than the diam of the rod. The fork should be figured for stress by assuming an average rectangular section at a point A-A (Fig. 47) and considering the total stress equal to the sum of the direct tensile or compressive stress and the stress due to bending. Total stress $= \dfrac{P_1 \times \sin 30°}{2b \times d} + \dfrac{6P_1 \times \cos 30° \times c}{2b \times d^2}$ which may be reduced to the form $\dfrac{P_1}{4bd^2}(d + 6a)$. The stress figured by this method may safely be 5,000 to 6,000 lb.

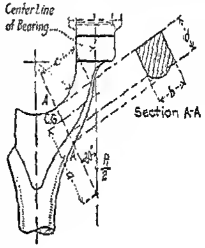

FIG. 47.

Bearings

White metal is cast in the bearing boxes at least ¼ in. thicker than required by the finished bearing to allow for hammering in. After the bear-

In built-up shafts the shafts and crankpins are shrunk into the webs. Square or round keys are always fitted in the shafts and sometimes in the pins.

Table 15. Proportions of Crank Webs for Built-up Shafts

Diameter bore for crankshaft	Diam shaft + 1½ in.
Diameter bore for crankpin	Diam pin + 1 in.
Metal around crankshaft	0.5 × diam shaft
Metal around crankpin	0.4 × diam pin
Thickness of webs if sections of shaft are interchangeable	0.68 × diam shaft
Thickness of webs if sections of shaft not interchangeable	Forward cylinder = 0.52 × diam shaft After cylinder = 0.73 × diam shaft.

Crankpins. It is usual to make the crankpin the same diameter as the crankshaft, although it is sometimes made larger to reduce the pressure, if it is desired to shorten the pin, or to reduce the stress, if a long pin is required to keep the pressure low. **Ratios of length to diameter** of pin vary in good practice from 0.95 to 1.0 for triple- and quadruple-expansion engines and from 1.0 to 1.1 for compound engines.

The pressure on the crankpin is figured from the thrust of the connecting rod, P_1, produced by the unbalanced pressure on the piston (see p. 1094). In computing the pressure the actual length of bearing surface of the connecting rod is used which is about ¼ in. less than the length of the pin. **Allowable pressures** per square inch are 300 to 325 lb for triple- and quadruple-expansion engines and 400 to 425 lb for compound engines. Some designers give consideration to the heat produced by the friction of the crankpin in proportioning its size, but unless the design is out of range of ordinary practice this is unnecessary.

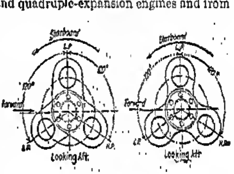

FIG. 60.

The **after crankpin**, through which the power from the forward cylinders all passes, should always be figured for stress. This pin is subjected to a bending moment produced by the torque from the forward cylinders applied at the forward end, and also to a bending moment from the torque produced by the after cylinder, applied at the middle of its length. These bending moments are combined and the resulting bending moment used in figuring the stress as follows:

Force from forward cylinders applied at forward end of pin,

$$F_1 = \frac{\text{ihp of forward cylinders} \times 33{,}000 \times 12}{2 \times \pi \times r \times \text{rpm}} \times C$$

Force from after cylinder applied at middle of pin,

$$F_2 = \frac{\text{ihp of after cylinder} \times 33{,}000 \times 12}{2 \times S \times \text{rpm}} \times 1.1$$

ing is bored out, it is scraped preferably to its own journal. The metal is held in place by dovetails $\frac{1}{4}$ to $\frac{1}{2}$ in. deep, arranged in a manner similar to that shown in *Fig. 48.* The **total thickness** of white metal should be approximately as follows: $\frac{9}{16}$ in. for 10-in. to $\frac{3}{4}$ in. for 20-in. main bearings and crankpins; $\frac{1}{2}$ in. for 7- to 15-in. and $\frac{5}{8}$ in. for 16- to 22-in. steady bearings; $\frac{3}{8}$ in. for 5-in. to $\frac{5}{8}$. in for 10-in. crosshead pins; $\frac{9}{16}$ to $\frac{3}{4}$ in. for thrust shoes and about $\frac{1}{2}$ in. for crosshead slippers and other flat surfaces.

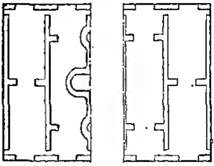

Fig. 48.—Dovetails securing white metal in bearings.

Main Bearings. Two bearings to each cylinder or crank are usual although, in order to shorten the engine and save weight, one bearing is often used between two cranks, in which case it is made longer than ordinarily required, or the bearing may be in two parts covered by the same cap, with a short distance between them. The **bottom boxes** may be cast steel, brass, or cast iron, lined with white metal. In naval, and sometimes in merchant engines, a separate cylindrical brass casting lined with white metal is used

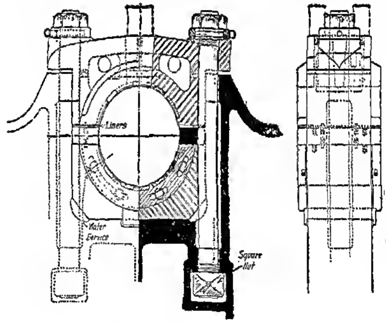

Fig. 49.

as shown in Fig. 49. This permits the bottom bearing to be rolled out for examination or repairs without taking up the crankshaft as is necessary with bearings of the type shown in Fig. 50. The **caps** are made either in one piece of cast steel or cast iron lined with white metal as shown in Fig. 49,

where r = radius of crank, in.

S = stroke, in.

C = ratio to max. to mean twisting moment as given in Table 14.

Let L = the length of crank pin in in., then maximum bending moment on after pin, $B_m = F_1 \times L + F_2 \times \frac{L}{2}$. Stress in pin $= B_m \div R_b$ where R_b = resistance of the pin to bending $= D^3 \div 10.2$ for solid pins and $(D^4 - d^4) \div 10.2D$ for hollow pins in which D = diameter of pin and d = diameter of hole. Stress in the crankpin computed by this method should not exceed 5,000 psi for merchant engines.

Thrust Shafts. The **diameter** is determined by the Classification Society rules, but it should be figured for stress due to combined bending and twisting, the bending moment being produced by its own weight between centers of the end bearings. The maximum twisting moment, T, will correspond to the value given under crankshafts. Maximum bending moment $= (W \times L) \div 8$, where W is the weight and L is length of shaft between centers of bearings in inches. The equivalent twisting moment and stress may then be found, as shown under crankshaft (p. 1106). Stresses of 5,000 to 6,000 psi are allowable in merchant work. For **number of thrust collars** see Thrust Bearings, p. 1101. In order to be stiff and not deflect the **diameter of the thrust, collars** should not exceed 1.45 to 1.65 times the diam of the shaft. With collars of these proportions pressures per square inch of 65 lb for the smaller ratio to 40 lb for the larger ratio may be carried safely. For the same reason the **thickness of collars** should not be less than 0.6 to 0.5 times the height. To provide sufficient space for stiff thrust shoes the **space between collars** should be 2.3 to 2.6 times the thickness of the collars for cast-iron and 1.4 to 1.6 for cast-steel shoes.

Line Shafts. The **diameter** is determined by the Classification Society rules but it should be figured for stress by the method given under Thrust Shaft. If the stress exceeds 5,000 psi for small or 6,000 lb for large shafts, the length between bearings should be reduced. In any event the **over-all unsupported length of line shafts** should not exceed 20 ft to avoid deflection.

Propeller Shafts. The **diameter** is determined by the Classification Society rules but the stresses due to combined twisting and bending should always be calculated. The maximum twisting moment is the same as given under crankshafts and the bending moment is produced by the weight of the shaft. The bending moment $= (2W \times L) \div 8$, in which W = weight of shaft between bearings, including brass sleeves, if fitted, and L = length in in. between centers of bearings. The factor 2, according to Seaton, is added for rough weather. Stress = equivalent twisting moment ÷ resistance to twisting. The stress in the after or overhung end of the shaft due to combined twisting and bending should also be computed. The bending moment $= W_1 \times L_1$, where W_1 = weight of propeller and shaft aft of the bearing, and L_1 = distance in in. from center of propeller to 3 in. inside of bearing. Stress = equivalent twisting moment ÷ resistance to twisting. (The brass sleeve should not be included in figuring the resistance.) Stresses in propeller shafts between bearings or in the overhung end should not exceed 5,000 psi for small and 6,000 lb for large shafts. Propeller shafts are fitted with brass sleeves in the stern-tube or strut bearings, the thickness of which should not

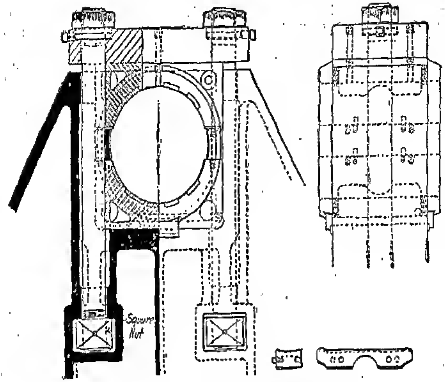

FIG. 50.—Types of main bearings.

or consist of a box of cast steel, cast iron, or brass held in place by a forged-steel keeper as shown in Fig. 50. Another type of main bearing is shown in Fig. 51. In this type the cap has lugs fitted over the bedplate to strengthen the bedplate against side thrust from the shaft. The distance pieces between the bottom brass and the cap prevent the bottom brass from nipping the shaft in case the bearing heats. Unless bearings are unusually long, two **bolts** are sufficient to secure the cap. The caps are fitted with **oil boxes** and a **handhole** with cover for the purpose of feeling the shaft and for applying cold water directly to the shaft in case the bearing warms up. The bottom boxes and sometimes the caps are cored for water circulation except in small engines.

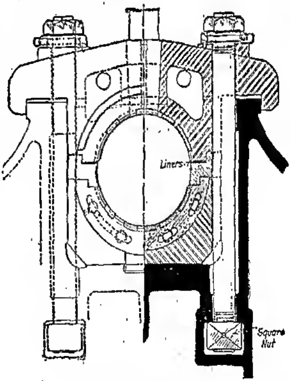

FIG. 51.—Main bearing.

be less than $\frac{3}{4}$ in. for all sizes of shafts up to 18 in., and 1 in. for shafts above 18 in. diam.

It is usual to cover the shaft between bearings with **brass sleeves**, the thickness of which may be about one-half that of the bearing sleeves. When brass sleeves are made in several sections the joints between the sections are scarfed leaving about $\frac{1}{8}$ in. open space for burning in or calking full of soft copper as shown in Fig. 61. In twin-screw vessels where struts are used and the propeller shafts are accessible, the shafts between bearing sleeves are often protected by wrapping with marlin or painting with anticorrosive paint.

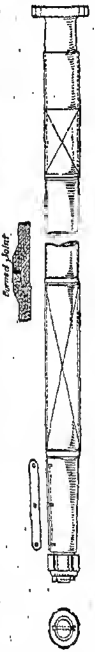

FIG. 61.—Propeller shaft.

Flanged Shaft Couplings. The diameter of the coupling flanges on crank, thrust, line, and propeller shafts is about 1.8 to 2 times diameter of shaft and the thickness about 0.23 to 0.28 times diameter of shaft but the couplings **should be proportioned from the size of bolts required.** The bolts must be of a size to safely resist the shear produced by the maximum twisting moment, T.

$$\text{Stress} = T \div n \times a \times r$$

where n = number of bolts
a = area of each bolt at face of coupling
r = radius of pitch circle

Allowable stress is 5,000 to 6,000 lb. **Six bolts are used unless** a greater number is required to avoid excessive size. Coupling bolts are tapered as shown in Fig. 62 except in interchangeable crankshafts in which case they must be straight as shown in Fig. 63. If diameter of bolt at face of coupling = A, then proportions of couplings and bolts when six bolts are used will be as follows: Thickness of coupling, $B = 1.2A$; distance from outside of shaft to pitch circle, $D = 0.9A$; distance to outside of coupling, C = from $2\frac{1}{8}$ in. for a 2-in. bolt to $3\frac{3}{8}$ in. for a $3\frac{1}{2}$-in. bolt; diameter of thread, $F = 0.75A$; depth of nut, $G = 0.75A$; depth of head for straight bolts, M = 0.7 to $0.65A$; size of head cross corners, $N = 1.38A$; taper for tapered bolts = $\frac{3}{4}$ in. per ft on diameter.

Clamp Shaft Couplings. When the propeller shaft is too long to be withdrawn inboard or if it is desired for other reasons to withdraw it outboard, a removable coupling of the clamp type of cast or forged steel as shown in Fig. 64 is used. The two fore-and-aft keys in each shaft transmit the torque and should be figured for shear from the maximum twisting moment as shown under Propeller Shafts, p. 1108. The diameter of coupling is from 1.7 to 2.0 times the diameter of shaft. The length must be sufficient to keep the key stresses within the allowable limit and is usually from 3 to 4 times the

The maximum pressure on the main bearings is produced by the unbalanced load and occurs twice each revolution, once upward and once downward, and is usually taken as the basis of figuring the pressure for purposes of design. The allowable pressure per square inch from the unbalanced load taken by two bearings runs from 125 to 175 lb. The ratio of length to diameter of main bearings is 1.0 to 1.15. The unbalanced load is not a true measure of the load on the bearings, but as it operates in the nature of a blow tending to destroy the oil film and bring the shaft and bearing metal into direct contact, it is always well to figure pressures in this way in addition to any other method used.

The true load on the main bearings is a function of the power passing through them and increases from forward to aft, as the power from the for-

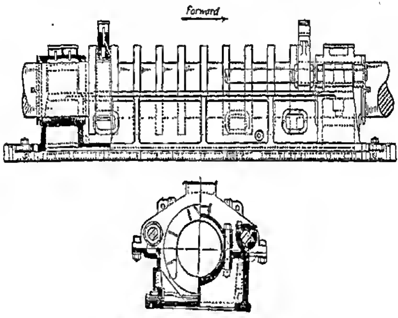

Fig. 52.—Thrust bearing, horseshoe type.

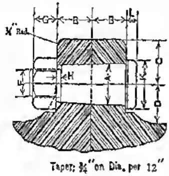
ward cylinders exerts a turning force on the after crank webs, which is transmitted to the bearings. Higher pressure per square inch is allowable on the after bearings as the turning force transmitted through them is more uniform and, therefore, is more evenly distributed around the bearing. In designing, however, it is usual to proportion the bearings on the average load and make all bearings the same length except the extreme forward bearing, which, having no power passing through it, frequently is made 10 per cent shorter than the intermediate bearings. For a similar reason it is desirable to make the extreme after bearing, through which all the power passes, 10 percent longer than the intermediate bearings. The average load on each bearing, from the power, is $\frac{\text{ihp} \times 33{,}000}{P.S. \times \text{no. bearings}}$ The allowable pressure per square inch from mean load runs from 80 to 120 lb. In the bearing pressures given above consideration has not been given to the weight and inertia of the crankshaft and reciprocating parts, or the centrifugal force. The pressure due to weight amounts to an additional 40 to 60 psi, but the effects of inertia and

diameter of shaft. The bolts should be as close to the shaft as possible and large enough to cause the coupling halves to grip the shaft tightly. The bolts are sometimes heated through the openings in the sides of the coupling while tightening up, in which case there will be a stress due to contraction in addition to the initial tension. The following formula adapted from Bauer gives the total area of all bolts on both sides at bottom of threads: Area $= C \times l \times (D - d) \div 2$, in which D, d, and l = outside diameter, bore, and length of coupling, respectively, and C is a constant = 0.25 to 0.35. When going astern, the propeller thrust is carried by projections on the inside of the coupling which fit into grooves turned in the shafts. These projections and the metal between the grooves and the ends of the shafts should be figured



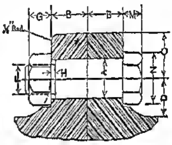


Fig. 62. Fig. 63.
Proportions of shaft couplings and bolts.

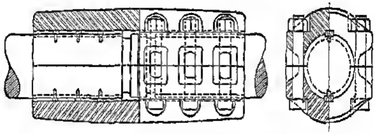

Fig. 64.—Clamp shaft coupling.

for shear and crushing due to the astern propeller thrust. Astern thrust in pounds $= \dfrac{\text{astern ihp} \times 33{,}000}{V \times 101.3}$ where V = astern speed of the ship in knots. The astern ihp may be taken as 80 per cent of the ahead ihp and V as 60 per cent of the ahead full speed.

Shaft Brake. In twin-screw and sometimes in single-screw vessels a brake similar to that shown in Fig. 65 is fitted to a shaft coupling aft of the thrust bearing to keep the shaft from turning while making repairs, or, in twin-screw vessels, to keep one shaft from turning while under way with the other engine.

Valve Gear

The two general classes of valve gears which permit of reversal are (1) link motion with eccentrics and (2) radial gears with or without eccentrics.

centrifugal force are small. Some designers, in determining allowable bearing pressures, take into account the product of the pressure and the rubbing speed of the bearings, but for merchant marine engines this is not considered necessary unless the engines are of a size and speed beyond the range of ordinary practice.

Main bearing caps and bolts must be proportioned for the maximum unbalanced load, P. The tensile stress in the bolts $= P \div (2n \times a)$ where n is number of bolts in one bearing and a is area at bottom of threads. The stress in the bolts, on account of the intermittent and suddenly applied load should not exceed 3,500 lb. The cap is figured as a beam loaded in the middle and supported at the ends. Stress $= Pl \div (8 \times 2R)$ for caps cast in a single piece, where l is distance between bolts, and R is section modulus which is determined by the method given on p. 1071. The section modulus is always figured under the white metal and the handhole and oil hole taken out. If the cap consists of a box with a keeper, it is considered that the separate box has the effect of making the load on the keeper a mean between concen-

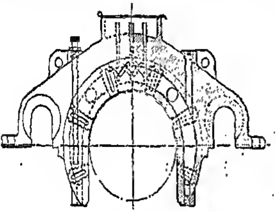

Fig. 53.

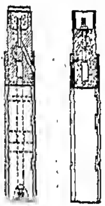

Fig. 54.

Thrust shoes.

trated and distributed load, and the load is assumed as all being taken by the keeper and stress $= Pl \div (10 \times 2R)$. On account of the intermittent and suddenly applied load and to secure stiffness, the stresses in caps should not exceed 2,500 psi for cast steel, 1,500 for cast iron, and 3,500 for a forged-steel keeper.

Thrust Bearings. The **horseshoe type** of thrust bearing (Fig. 52) is generally used with reciprocating engines as the nuts on the side rods provide means of adjustment. The **number of shoes and their area** are determined from the indicated thrust T, which $= \dfrac{\text{ihp} \times 33{,}000}{\text{rpm} \times P \times \%}$ or $\dfrac{\text{ihp} \times 33{,}000}{S \times 101.3}$ where P is pitch of propeller in feet, % is percent slip, and S is speed of the vessel in knots. For **diameter of thrust collars** see p. 1108. In this type of bearing the effective area of the thrust shoe is only about 70 percent of the annular area of the thrust collar. The **pressure on the shoes** is usually 40 to 60 psi, but with very stiff thrust collars and shoes pressure as high as 65 lb may be carried safely. The thrust shoes (Fig. 53) are cored for water circulation and are usually of cast-iron, although sometimes of cast steel, and are lined with white metal on both faces. The **thickness of the**

In America **Stephenson link motion** with two eccentrics is the most common type of valve gear used but **radial gears of the Marshall type,** with one eccentric, and the **Joy type,** worked by links from the connecting rod, are frequently used. With Stephenson link motion the valves are in the fore-and-aft center line of the cylinders although sometimes the high-pressure valve is placed on the side of the cylinder and the valve motion transmitted from the links through a rocker arm With the Marshall and Joy types the valves are on the side of the cylinders and hence the fore-and-aft length of the engine is less. A valve gear to be perfect would have a motion that would instantly open the valve wide at the beginning of the stroke and instantly close it at the point of cutoff without wire drawing; it would also instantly open it wide to exhaust at the end of the stroke and instantly close it when exhaust is completed. To more nearly attain this motion, **double-ported and trick valves** are often introduced. This motion is more nearly approached by radial valve gears than by link motion. With radial valve gears the lead is constant or nearly constant for all cutoffs. This is considered a very desirable feature by some designers.

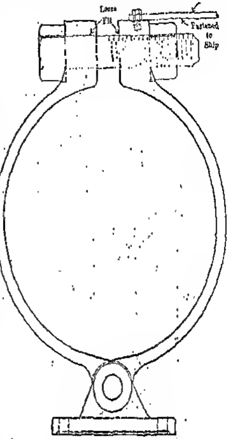

Fig. 65.—Shaft brake.

Stephenson Link Motion. In this type of valve gear there are two eccentrics keyed to the crankshaft, each operating an eccentric rod connected to a common link as shown in Fig. 106. The positions of the eccentrics are such that one eccentric rod operates the valve for going ahead and the other for going astern, the common link acting as the means for changing from one to the other. The valve stem is connected to the link block which slides on the link and changes the positions of the eccentric rods relative to the valve stem. When the block is in mid-position, there is practically no motion imparted to the valve and the engine stops. When it is in extreme position on the **go-ahead** eccentric rod the link is in **full gear** and **linked up** when the link block is in any position between extreme and mid-positions. Reversal is accomplished by moving the links by the suspension rods so that the sliding block is changed from the go-ahead to the **go-astern** eccentric rod which reverses the motion of the valve. Each cylinder may be **linked up independently** by means of the screw in the slotted reverse arm thus moving the links to bring the sliding block into the desired intermediate position. When linked up both eccentrics act on the valve and the motion is equivalent to that of an eccentric with less eccentricity and greater angle of advance

thrust shoe, including the babbitt, should be 2.3 to 2.6 times the thickness of the thrust collar for cast iron and 1.4 to 1.6 for cast steel. Sometimes instead of the customary dovetailed babbitted surface, a loose babbitt or bronze face is secured to the "go-astern" side of the thrust shoe by screws as shown in Fig. 54. Liners may then be inserted behind the face to take up wear. In calculating the **stress in the thrust shoe** it is considered as a beam supported at the centers of the side rods, the load being taken as a mean between concentrated and distributed. Bending moment $= TL \div 10n$, where L = distance between side rods in in. and n = no. of shoes. The modulus of the section at the center is found in accordance with the method given on p. 1071. Stress = bending moment ÷ section modulus. In order to avoid deflection, which would cause unequal bearing on the surface, stresses in thrust shoes should be kept low, good practice being not over 1,500 psi for cast iron and not over 3,000 lb for cast steel. The tensile **stress in the side rods** is calculated by dividing the total indicated thrust by the area of the

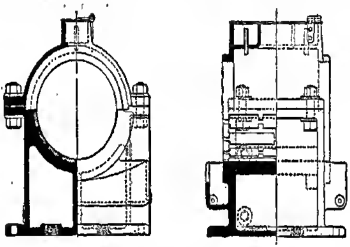

FIG. 55.—Line-shaft steady bearing.

rods at the bottom of the thread. A stress of 5,000 to 6,000 psi is allowable for either steel or bronze rods. **Steady bearings** of the same design as the line-shaft steady bearings are fitted at each end of the thrust bearing bedplate as shown in Fig. 52. The length of these bearings is 1.0 to 1.1 × diam of shaft. Sometimes the cap is lined with white metal but this is unnecessary. A stuffing box is fitted around the lower half of the shaft to retain the oil in the thrust-bearing bedplate. A pipe coil for water circulation for cooling the oil is fitted in the bottom of the thrust-bearing bedplate.

The **all-round type** of thrust bearing is occasionally used. To permit of adjustment, the "go-ahead" and "go-astern" bearings are separate, although both are fitted on a common bedplate. In this type the bearing surface covers the entire annulus of the collar, and as the collars on the shaft, owing to their form, are less liable to deflect, they may be made of larger diameter, necessitating the use of fewer shoes to maintain the same pressure per square inch. These bearings, however, lack the adjustability of the horseshoe type and are now seldom used in marine work.

Sole Plate. The thrust bearing is bolted down, through elliptical holes, on a cast-iron sole plate which is riveted to the hull foundation. Adjusting

resulting in shorter valve travel and a change in lead, cutoff, release, and compression. The change in these functions is shown by the valve diagram.

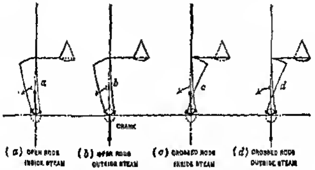

FIG. 66.—Open and crossed eccentric rods.

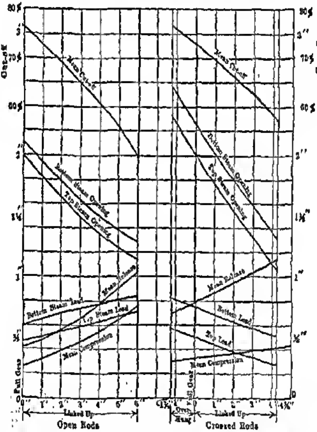

FIG. 67.—Changes in valve functions for open and crossed rods.

The go-astern eccentric is set at the same angle relative to the crank as the go-ahead eccentric but on the opposite side of the crank.

Open and Crossed Rods. With the eccentricity toward the links, the eccentric rods are open when arranged as shown at *a* and *b*, and crossed when arranged as shown at *c* and *d* (Fig. 66). In full gear the valve motion

wedges are fitted at each end between the bearing flanges and projections on the sole plate. It is very important that the foundation under the sole plate be strong and rigid to avoid deflection. Sometimes to ensure rigidity it is preferred to cast the sole plate with V-shaped legs on the forward end for bolting to the main engine bedplate. For merchant vessels of low power it is satisfactory to omit the sole plate and to bolt the thrust bearing to the hull foundation on liners through which the bolts pass, chocks being riveted forward and aft of the bearing and liners driven up hard against the bearing flanges to lock the whole solid after bearing is adjusted. Low stresses (not over 4,000 psi in single shear) should be allowed in the rivets securing the sole plate and in the holding-down bolts securing the bearing.

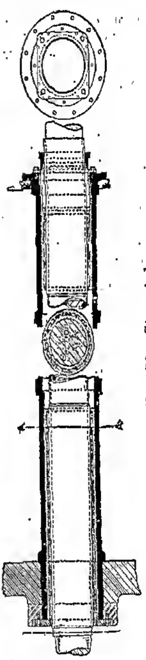

FIG. 56.—Stern tube.

Line-shaft Steady or Spring Bearings. It is customary to make steady bearings the same diameter as the shaft, it being unnecessary to increase the shaft in the bearing even if it is desired to leave the rest of the shaft rough-turned; only one bearing is generally used to each section of shaft, but with large shafts a bearing is sometimes fitted at each end of each shaft to facilitate lining up and handling. The **lengths of steady bearings** vary from 1.25 to 1.5 diameters and the **pressures per square inch of projected area** due to the weight of the shaft run from 35 to 50 lb. If the distance between bearings is too great, the shaft may deflect due to its weight and cause heating of the bearings. With only one bearing per shaft a **safe length between center of bearings** in feet $= c\sqrt{d}$ in which d = diameter of shaft in in. and c = 5 to 5.5. Figure 55 shows a typical steady bearing. The **pedestal** is of cast iron lined with white metal, and provided with an oil receptacle. The **cap**, which is usually merely a shell almost touching the shaft at each end to keep out dirt, has wick-feed oil boxes and a **handhole** for feeling the shaft. The bearings are sometimes piped for water circulation. Caps are secured by four **bolts**, the diameters of which vary from 1 in. for an 8-in. bearing to $1\frac{1}{2}$ in. for an 18-in. bearing. For the same size bearings the **holding-down bolts** vary from 1 to $1\frac{1}{4}$ in. diameter, pitched about 6 diameters. Ring oiling is sometimes used.

Stern tubes in merchant work are of cast iron and in one piece unless very long (Fig. 56). The **thickness of the casting** in the stern frame and between bearings varies from $1\frac{1}{2}$ in. for a 10-in. shaft to $2\frac{1}{2}$ in. for a 20-in. shaft. The **minimum length of the after bearing** is 4 times the diameter of propeller shaft under the bearing sleeve according to Lloyd's rules, but this

is the same for open as for crossed rods but, when the gear is linked up, the effect on the valve functions is materially different. The curves in Fig. 67 show that with open rods a greater range of cutoff may be obtained with a smaller reduction of port opening than with crossed rods. As the gear with open rods is linked up, the lead increases while with crossed rods it decreases and may become negative. Linking up with crossed rods decreases the valve travel very rapidly with consequent reduction of both steam and exhaust port openings and therefore crossed rods are not as well adapted for expansive working as open rods. With crossed rods the links are thrown toward the back of the engine when in ahead gear, which leaves the front of the engine open for oiling and inspection. Also the suspension rods are much longer which reduces the slotting action of the link block. Most marine engines are fitted with open rods.

Slip of the Link Block. In laying out a valve gear the slip or slotting action of the link block on the links should be given consideration. Although this slip has no practical effect on the action of the valve, the length of the suspension rods and the point of suspension should be chosen to reduce this action as much as possible on account of wear. The nearer the link block to the point of suspension the smaller will be the slip. If the links are suspended directly over the position of the link block when in full gear ahead, the slip may be considerable when the engine is reversed but this is of little importance if it is a minimum for the usual working position of the links. When the probable location of the reverse arm has been determined, the path of the point of suspension for one complete revolution should be plotted for full gear ahead and astern and maximum linked-up position ahead and astern and clearances carefully checked. By examination of these loops, examples of which are shown in Fig. 68, it may be possible to choose a position of the reverse arm which will reduce the slotting action.

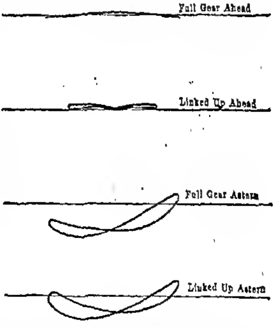

FIG. 68.—Slip of the link block.

Marshall Radial Valve Gear. This type of marine-engine valve gear as usually constructed in America has the valve rod connected to the eccentric rod outside of the point of attachment of the guide link while European practice is to make the connection between the guide link and the eccentric. The arrangement of this gear for each cylinder consists of one eccentric mounted on the crankshaft, giving motion to a short and massive eccentric rod A (Fig. 69) which is guided at a by the link B and is connected at b to the valve rod D. The guide link B is supported at d by the bell crank

sometimes is made longer. **The length of the forward bearing** depends on the length of the stern tube, but the minimum length is 1½ times the diameter of shaft. **The pressure due to weight** of the shaft, sleeve, and propeller should not exceed 30 psi for the after bearing and 20 lb for the forward bearing. In all cases a steady bearing is fitted on the line shaft as close as possible to the inboard coupling. The stern-tube bearings are usually of lignum vitae contained in brass bushings, made in halves, the joints being in the horizontal plane slightly inclined fore and aft to facilitate withdrawal. **The thickness of the wood,** which always bears on the end of the grain, runs from 1 in. for a 10-in. shaft to 1¼ in. for a 20-in. shaft. **The thickness of the brass bushing** under the wood for the same size shafts is about ½ and ¾ in. The stern tube is held in place in the stern frame by a cast- or forged-steel nut in which there are holes or slots for a spanner wrench for tightening up. Four threads per inch are used for nuts of all sizes. The thickness of the nut should be about 3¼ in. for a 10-in. shaft and 6½ in. for a 20-in. shaft. At the forward end of the stern tube is fitted a **stuffing box** of the usual type for soft packing. Very often a bronze or cast-iron bushing is substituted for the forward lignum vitae bearing.

No lubricant other than water is required for stern tubes with lignum vitae bearings. There should be a pipe connection to one of the salt-water pressure pumps in the engine room for washing out the stern tube and also a connection for draining the space between the forward and after bearings. Sometimes the after bearing is babbitted and the forward bearing bronze bushed, in which case a protecting stuffing box must be fitted between the propeller and the after end of the stern tube to keep out sand and dirt. With these stern tubes oil is used for lubrication. There are several patented stern tubes and protective stuffing boxes on the market.

Strut Bearings. In twin-screw vessels in which the stern tube is not carried back to the propeller a separate bearing is carried in the strut for taking the weight of the shaft and propeller. The length of the bearing, the thicknesses of the wood and the brass bushing, and the pressure per square inch correspond to the figures given for the after stern-tube bearing.

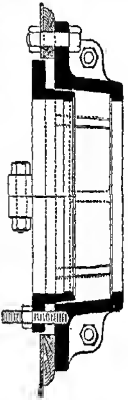

FIG. 57.—Bulkhead stuffing box.

Lignum vitae is a greenish-brown, hard, heavy wood of specific gravity, 1.10. It is used for stern-tube and strut bearings, and makes an excellent low-pressure bearing when **lubricated by** the free circulation of water. Lignum vitae **for use in bearings** should be generally straight, sound, and well seasoned; it **should be free from** injurious shakes, wormholes, excessive sap, large or unsound **knots**, and other injurious defects. Ordinary season checks, small amounts of sap, slight heart and ring shakes are not generally considered defects.

Bulkhead stuffing boxes of cast iron are fitted where line shafting passes through a water-tight bulkhead (Fig. 57). The box and gland are in halves.

lever C having its axis at c and connected by the rod F to the reverse arm G. The valve rod D may be connected to the valve stem direct or through a rocker arm. The gear is linked up by shortening the valve travel which is done by means of the adjustment block in the bell-crank lever C. The movement of the point b is an ellipse as shown inclined to the horizontal in one direction for ahead motion and in the opposite direction for astern motion, the change being effected by the reversing engine through the reversing rod F. The angle between the eccentric and the crank is either 0 or 180 deg according to whether the valve is driven direct or through a rocker arm or whether it takes steam inside or outside. Lead is constant, and a sharp cut-off and good steam distribution are obtained but to the curvature at the path of the point a, the top and bottom cut-offs are unequal. The large number of joints subject to wear results in excessive lost motion and frequent adjustments must be made. The oval-valve diagram is used for this type of gear and it is usually worked out by means of a simple model.

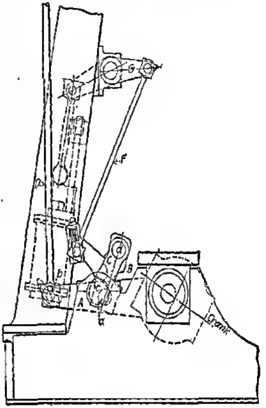

Fig. 69.—Marshall radial valve gear.

Joy Radial Gear. In this type of valve gear no eccentrics are used, the movement being taken from the connecting rod by a series of links. By utilizing the reciprocating and vibrating actions of the rod a movement results which gives almost equal cutoff for both sides of the piston for all points of expansion, less compression at short cutoff, and much quicker action at the points of admission and cutoff than is given by Stephenson link motion. Lead is constant. The vibrating link A (Fig. 70) is connected to a point on the connecting rod and to the radius rod B. The movement of the point a is an ellipse and of the point b an arc of a circle as shown. Another lever C with a fulcrum at d is connected at c to a point on the vibrating lever and at e to the valve link E which actuates the valve stem G. The fulcrum d is connected to the reverse lever D or to a link block sliding in a slotted link. The movement of the point e is an ellipse, the inclination of which from the horizontal, as effected by the position of the reverse lever D, or slotted link, governs the degree of expansion. The engine is reversed by inclining the axis of this ellipse the other way by means of the reverse lever through the link F.

The stuffing box is carried on a portable plate in halves large enough to ship the shafts and bearings. Soft packing is used.

Shafting

Arrangement. The location of the after end of the shafting is determined by the diameter and the depth of immersion of the propeller. In single-screw vessels a clearance of 4 to 6 in. must be allowed between the tips of the propeller and the stern frame shoe. In twin-screw vessels ample clearance between the tips of the propellers and the hull must be allowed (see p. 1425). The height of the **forward end of the shafting** is determined by the depth necessary for a strong and rigid foundation under the main engine bedplate. Shafting is kept parallel with the base line of the vessel except where the inner bottom or the water tanks under the engine makes this impossible. In twin-screw vessels it is often impossible owing to the arrangement of the machinery, to keep the shafting parallel in the horizontal plane.

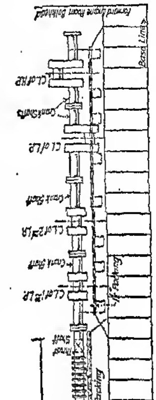

FIG. 58.—Arrangement of shafting.

The shaft tunnel is fitted its entire length with a platform from which the bearings may be attended. The forward end of the shaft tunnel is isolated from the engine room by a sliding watertight door operated from above. Overhead in the tunnel are located eyebolts or other lifting gear for handling the propeller and thrust shafts and the stern-tube bearings. The propeller shaft is drawn inboard for examination unless its length is prohibitive. A water service pipe is carried through the tunnel with a connection to each bearing and to the stern-tube stuffing box. This pipe is usually led so it can be used as a handrail. Figure 58 shows the arrangement of shafting for a single-screw vessel with the machinery located in the stern.

Crankshafts for merchant engines are usually of the "built-up" type, *i.e.*, the pieces of shaft, webs, and pins are forged separately and shrunk together. For naval engines, yachts, and other engines where saving of weight and space is important, crankshafts are "solid-forged" and usually hollow. In order that one spare section of crankshaft may serve for any crank, the sections are often made interchangeable and sometimes interchangeable and reversible, *i.e.*, one spare section will serve for any crank with either end forward. The over-all dimensions of cylinders and

For this type of valve gear the **oval-valve diagram** is used and it is best worked out by means of a simple model. The defects of the Joy gear are the large number of joints subject to wear, resulting in excessive lost motion, and the difficulty of inspecting and taking care of the crosshead and crankpin owing to the obstruction of the moving parts while the engine is running.

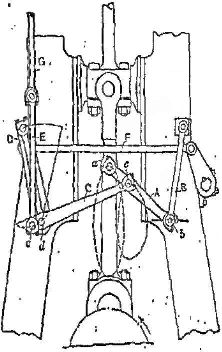

FIG. 70.—Joy radial valve gear.

Action of the Valve. The successful operation of the engine depends upon the proper design and setting of the valves. The action of the valve is the same whether piston or flat slide valves are used, and the elementary principles apply to both. In mid-position, the valve not only covers the steam ports, but overlaps the edges of the ports, as shown in Fig. 71. The amount of overlap a, on the steam side is the **steam lap** and on the exhaust side b, the **exhaust lap.** The exhaust lap b is **positive** if overlapping the edge of the port and **negative** when not covering the port. The other elements are c, **steam port width;** d, **maximum steam port opening;** e, **exhaust port width;** f, **minimum exhaust port opening;** and g, **half travel.** The complete cycle of distribution of steam in the cylinder consists of admission, expansion, release, and compression. Admission begins through c, when the outer edge of the valve has traveled a distance equal to the steam lap a and uncovered the edge of the steam port (**point of admission**), and ends when the valve has reached this point again, traveling in the opposite direction (**point of cutoff**). Expansion then takes place until the inner edge of the valve has uncovered the edge of the steam port to exhaust (**point of release**). Exhaust continues until the valve closes the port traveling in the opposite direction (**point of compression**).

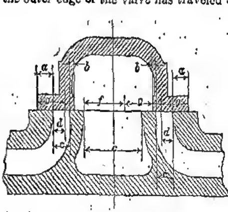

FIG. 71.—Elementary slide valve.

From this point compression takes place until the valve is again opened to admission. The maximum steam port opening d is usually less than the width of port c, and is reached when the valve has traveled its maximum distance from mid-position. The amount which the steam port is open when the piston is at the end of the stroke is the **lead,** or steam lead. Similarly the amount which the exhaust port is open is the exhaust lead, commonly

bedplate are increased if the sections of crankshaft are made interchangeable, or interchangeable and reversible. This question is discussed on p. 1153.

The diameter of the crankshaft for a merchant engine is determined from the rules of the Classification Society under which the vessel is constructed, but the designer should always calculate the stress in the after end of the shaft produced by the combined bending and twisting moment. Maximum twisting moment in inch-pounds, $T = \frac{63{,}000 \times \text{ihp}}{\text{rpm}} \times C$, where C = ratio of the maximum to the mean twisting moment. This ratio varies with the number of cranks, as shown in Table 14. The bending moment is produced by the twisting moment, which, for all practical purposes, may be taken the same as T, considered at the middle of the crankpin. Then maximum bending moment, $B = T \times L \div 8 \times r$, where L = distance between edges of bearings of after crank in in. + 1 in. and r = radius of crank in in. Then equivalent maximum twisting moment, $T_e = B + B\sqrt{1 + (T \div B)^2}$.

Stress in shaft = $T_e \div R_t$, where R_t is resistance of the shaft to twisting $= D^3 \div 5.1$ for solid shafts and $(D^4 - d^4) \div 5.1D$ for hollow shafts, in which D = diameter of shaft and d = diameter of hole. Stress should not exceed 6,000 psi although it is often less than this, due to the desire of owners to have shafts larger than required by the Classification Society rules.

Table 14. Ratio of Maximun to Mean Twisting Moment

Type of Engine	Ratio for Average Cut-off of 70 Percent in H-p Cylinders
One-crank	2.00
Two-crank	1.50
Three-crank	1.33
Four-crank	1.25

The effect of inertia is not considered in the above ratios. According to Bragg, inertia may increase the ratio for three-crank engines as much as 18 per cent, while for engines with cranks at 180 and 90 deg, the inertia effects are nearly balanced.

Crank webs for merchant engines are usually of the type shown in Fig. 59, with straight sides, although they are sometimes made as shown in Fig. 60

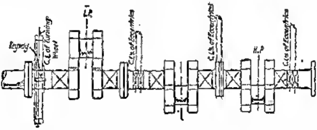

Fig. 59.—Crankshaft.

to save weight; the weight saved, however, does not justify the extra labor involved. Crank webs are subjected to a bending stress in the direction of rotation due to the maximum twisting moment and also to a bending stress in a fore-and-aft direction owing to the unbalanced load on the crankpin. These stresses, however, are small and need not be computed, if the webs are proportioned by Table 15.

called release. To bring the edge of the valve into proper position relative to the edge of the steam port when the piston is at the end of the stroke, it is necessary to move the eccentric through an angle which will move the valve from its central position a distance equal to the steam lap plus the steam lead. This angle is called the **angle of advance.**

Valve Functions. If there were neither lap nor lead, the valve would be central each time the piston reached the end of the stroke and steam would enter the cylinder throughout one stroke and be exhausted throughout the next. There would be no expansion and no compression. The use of lap makes cutoff and expansion possible. It is customary to make the top steam lap slightly larger than the bottom lap to lessen the difference between the top and bottom cutoffs. Steam laps of 1 to 2½ in. are commonly used in marine engines. Positive **exhaust lap** retards the period of release and makes compression earlier while negative exhaust lap has the opposite effect. The amount of lap, whether positive or negative, is determined by the exhaust opening which should be wide open at the end of the stroke. Exhaust lap, if negative, should always be less than the steam lap to avoid a passage for steam from one end of the cylinder to the other at the moments of admission and cutoff. Frequently exhaust lap is zero but it may be as much as ± 1 in. **Steam lead** is generally settled according to the judgment of the designer. The inertia of the moving parts relative to the area of the piston should be taken into consideration in determining lead as ordinarily compression is not sufficient to overcome the inertia of the moving parts by the time the piston reaches the end of the stroke. Lead therefore helps to cushion the piston and should be greater for large than for small cylinders. It may vary from ⅛ in. in small high-pressure cylinders to 1½ in. in large low-pressure cylinders. On account of the angularity of the connecting rod the bottom lead is always made more than the top lead. Top lap plus lead must always equal bottom lap plus lead. As linking up increases the lead with open rods and decreases it with crossed rods, as shown in Fig. 67, normal lead is made greater with crossed rods. **Lead with Marshall, Joy, and other radial valve gears** is constant for all grades of expansion. The **cutoff** for equal power in each cylinder of a multiple-expansion engine depends on the relative volumes of the cylinders as discussed on p. 1066. With Stephenson link motion the bottom cutoff is from 5 to 9 percent less than the top cut off due to the angularity of the connecting rod. **Release**

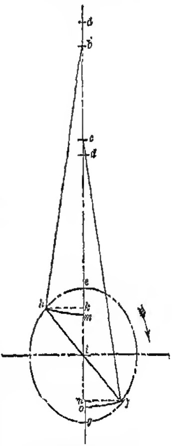

FIG. 72.—Effect of angularity of the connecting rod.

To Multiply by Logarithms. Find from the table the log of each factor, and add; the result will be the log of the product. Then find the product itself from the table.

EXAMPLE. To find $x = (4.098)(0.0002973)(72.1)$	$\log 4.098 = 0.6126$
	$\log 0.0002973 = 0.4732 - 4$
Answer: $x = 8.784 \times 10^{-2}$	$\log 72.1 = \underline{0.8579 + 1}$
$= 0.08784$	$\log x = 1.9437 - 3 = 0.9437 - 2.$

To Divide by Logarithms. First Method: Find from the table the log of the numerator and the log of the denominator, and subtract the second from the first; the result will be the logarithm of the quotient. Then find the quotient itself from the table.

EXAMPLE. To find $x = \dfrac{4.098}{0.0002973}$	$\log 4.098 = 0.6126$
	$\log 0.0002973 = \underline{0.4732 - 4}$
Answer: $x = 1.378 \times 10^4 = 13780$	$\log x = 0.1394 + 4$

In order to avoid negative mantissas in cases where a larger mantissa would have to be subtracted from a smaller, modify the upper logarithm by adding and subtracting 1.

EXAMPLE. To find $x = \dfrac{0.0291}{63.4}$	$\log 0.0291 = 0.4639 - 2 = 1.4639 - 3$
	$\log 63.4 = 0.8021 + 1 = \underline{0.8021 + 1}$
Answer: $x = 4.590 \times 10^{-4}$ $= 0.0004590$	$\log x = 0.6618 - 4$

But if the logarithms are written with the characteristics in front, and the "shop method" of subtraction is used (see p. 88), then no such special device is here required. Thus:

$$\log 0.0291 = \bar{2}.4639$$
$$\log 63.4 = \underline{1.8021}$$
$$\log x = \bar{4}.6618$$

To Divide by Logarithms. Second Method: Instead of subtracting the log of a number, it is often convenient to add the **cologarithm** of that number; the colog of N being defined by: $\text{colog } N = \log(1/N) = -\log N$.

To find the colog of a number, write the log. of the number in the standard form, and subtract it from $1.0000 - 1$, as in the following examples:

$$\begin{array}{rl} & 1.0000 - 1 \\ \log 69.5 = & \underline{0.8420 + 1} \\ \text{colog } 69.5 = & 0.1580 - 2 \end{array} \qquad \begin{array}{rl} & 1.0000 - 1 \\ \log 0.0002973 = & \underline{0.4732 - 4} \\ \text{colog } 0.0002973 = & 0.5268 + 3 \end{array}$$

This subtraction should be performed mentally. Thus, to subtract the mantissa, subtract each digit from 9 until the last non-zero digit is arrived at, and subtract this from 10; to subtract the characteristic, follow the regular rule of algebra ("reverse the sign and add"). Hence, if the logarithm itself is already written down, or can be read off from the table without interpolation, the cologarithm can be written down at once, by inspection. The use of cologarithms is not essential in logarithmic computation, but it often facilitates a compact arrangement of the work, especially in cases where the denominator of a fraction is itself the product of two or more factors.

To Find the nth Power of a Number by Logarithms. Find from the table the log of the number, and multiply it by n; the result will be the logarithm of the nth power of that number. Then find the power itself from the tables.

EXAMPLE 1. Find $x = (0.0291)^3$	$\log 0.0291 = 0.4639 - 2$
Answer: $x = 2.464 \times 10^{-5}$	$\underline{\quad 3}$
$= 0.00002464$	$\log x = 1.3917 - 6 = 0.3917 - 5$

EXAMPLE 2. Find $x = (0.0291)^{1.41}$ $\log 0.0291 = 0.4639 - 2 = -1.5361$

Answer: $x = 6.825 \times 10^{-3}$

$= 0.006825$

$$\begin{array}{r} -1.5361 \\ 1.41 \\ \hline 15361 \\ 61444 \\ 15361 \\ \hline \end{array}$$

$$\log x = -2.1659 = 0.8341 - 3$$

To Find the nth Root of a Number by Logarithms. Find from the table tho log of the number, and divide it by n; the result will be the log of the nth root of that number. Then find the root itself from the table.

EXAMPLE. Find $x = \sqrt[3]{4.098}$ $\log 4.098 = 0.6126$

Answer: $x = 1.600$ $\log x = 0.2042$

In order to avoid fractional characteristics, if the characteristic is not divisible by n, make it so divisible by adding and subtracting a suitable number before dividing.

EXAMPLE. Find $x = \sqrt[3]{0.0004590}$ $\log 0.0004590 = 0.6618 - 4$

$3)\underline{2.6618 - 6}$

Answer: $x = 7.714 \times 10^{-2}$

$= 0.07714$ $\log x = 0.8873 - 2$

But if the characteristic is positive, it is simpler to write it in front of the mantissa, and then divide directly.

THE SLIDE RULE

The slide rule is an indispensable aid in all problems in multiplication, division, proportion, squares, square roots, etc., in which a limited degree of accuracy is sufficient. The ordinary 10 in. Mannheim rule (see below) costs \$3 to \$4.50 and gives three significant figures correctly; the 20 in. rule (\$12.50) gives from three to four figures; the Fuller spiral rule (\$30) or the Thacher cylindrical rule (\$35) gives from four to five figures. For many problems the slide rule gives results more rapidly than a table of logarithms; it requires, however, more care in placing the decimal point in the answer. In all work with the slide rule, the position of the decimal point should be determined by inspection (see p. 89), only the sequence of digits being obtained from the instrument itself. Rapidity in the use of the instrument depends mainly on the skill with which the eye can estimate the values of the various divisions on the scale; expertness in this respect comes only with practice. The following explanations should be sufficient to permit the use of the ordinary slide rule successfully without previous experience and without knowledge of logarithms.

Multiplication and Division with a (Theoretical) Complete Logarithmic Scale. Consider a *complete* logarithmic scale (D, Fig. 1), assumed to extend indefinitely in both directions, only the main section, from 1 to 10, however, being usually available. Note that the divisions within the several sections are identical, except that the numeral attached to each division of any one section is ten times the numeral attached to the corresponding division in the preceding section. [The distances laid off from 1 are proportional to the logarithms of the corresponding numbers, the distance from 1 to 10 being taken as unity.] Consider also a duplicate scale C, numbered from 1 to 10, and arranged to slide along the fixed scale D as in the figures. By means of such a scale D and slide C any two numbers between 1 and 10 (and hence any two numbers whatever, with proper attention to the decimal point) can be multiplied or divided, as in the following examples.

(sometimes called exhaust lead) should be early enough to give a free passage for exhaust to avoid wire drawing; 7 to 16 percent is the range for marine engines. **Compression** should not be carried beyond the pressure of admission; it varies from about 6 percent in high-pressure cylinders to about 12 percent in low-pressure cylinders. The **angle of advance** is the lap angle plus **lead angle** and may range from 33 deg for high-pressure to 45 deg for low-pressure cylinders. With valves taking outside steam the eccentric precedes the crank 90 deg plus angle of advance, and with valves taking inside steam the eccentric follows the crank 90 deg minus angle of advance. Although the **angularity of the connecting rod** affects the position of the piston with reference to the crank, the length of the eccentric rod with reference to the throw of the eccentric is so great that the displacement of the valve is considered equivalent to the vertical travel of the center of the eccentric and the valve travel equal to twice the radius of the eccentric.

Valve Travel. It is important that the travel of the valve be kept as short as practicable to reduce frictional loss. The travel of a piston valve may be reduced by increasing the diameter and of a slide valve by making it double ported, or in case of very large cylinders with long strokes, triple ported. The valve travel of all cylinders is kept the same if possible but it is often found, when working out the valve diagram, that it is better to increase the travel of the low-pressure valve. The travel is usually 2 to 3 times the width of the steam port.

Angularity of the Connecting Rod. Inspection of Fig. 72 will show that, for the same angular position of the crank relative to the beginning of the stroke, the piston moves a much greater distance on the down stroke than on the up stroke. If Fig. 72 represents the positions of the piston and crank at cutoff, it is evident that with a connecting rod of infinite length, the piston would have traveled equal distances and ac and db would be equal to en and gk and the cutoffs would be equal; but the angularity of the connecting rod increases the cutoff on the down stroke and reduces it on the up stroke making $ac = eo$ and $db = gm$. Actually a movement of the crank of 120 deg, with a connecting rod length equal to 4 times the crank, corresponds to a cutoff or piston travel of 80 percent on the down stroke and 70 percent on the upstroke. To partly overcome this difference, the top steam lap is made larger than the bottom. However, this difference with Stephenson link motion can never be reduced below about 5 percent.

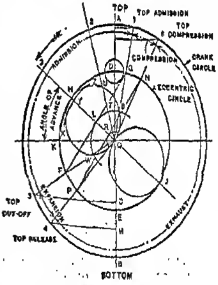

FIG. 73.—Construction of Zeuner valve diagram.

Zeuner Valve Diagram. In laying down a valve diagram the valve travel, cutoff, steam lead, and exhaust release are assumed and the other functions determined by trial. The Zeuner valve diagram is generally used for Stephenson link motion and is constructed as follows:

Lovekin Assistant Cylinders. In this type of balance cylinder (Fig. 85) the admission of steam to the underside of the piston is controlled by the movement of the piston past a steam port. The steam is taken directly from the chest and the action is automatic. Its purpose is to balance the inertia force of the valve gear on the down stroke as well as the weight, by

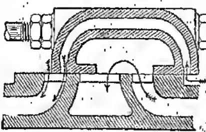

FIG. 83.—Trick slide valve.

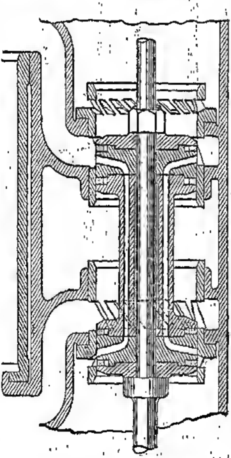

FIG. 84.—Trick piston valve.

compression of steam on the underside of the piston to a pressure higher than that of the valve chest. In cases where the inertia force is much greater than the weight of the valve gear, steam is also admitted on top of the piston to provide compression on the up stroke as well as the down stroke. In this case the steam required is only that necessary to replace the steam which condenses as there are no exhaust ports.

In Fig. 73 let the line AB be the direction of travel of the valve. With O as a center describe the circle DKE with radius equal to the eccentricity (full size) and also the crankpin circle $A3B$ reduced to a convenient scale. Assume A top and B bottom of stroke. Offset AC from A equal to the top cut-off and draw the corresponding crank position $O3$, using the length of the connecting rod reduced to scale, as a radius. With D as a center draw a circle with radius equal to the top steam lead and from F a line FG tangent to this circle. Bisect this line with a normal HJ through O. A circle HSO with HO as diameter will represent the movement of the valve from the central posi-

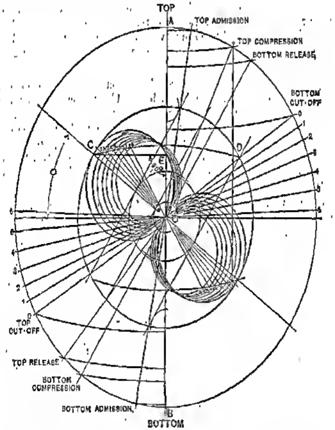

FIG. 74.—Zeuner valve diagram for open eccentric rods.

tion. The angle HOK is the **angle of advance**, LO the **steam lap**, and LH the **maximum steam opening** which occurs at crank position $O2$. The **steam opening for any other crank position** $O5$ is TU. Draw $O1$ through G which passes through the intersection of the steam lap circle WLS and the valve circle HSO. The line $O3$ also passes through the intersection of these circles. The points S and W, therefore, represent the **opening and closing of the valve**. Complete the construction for the bottom of the stroke in a similar manner. Offset BM from B equal to the top exhaust release and draw the crank position $O4$. Also draw $O6$ making angle $6O2$ equal to angle $4O2$. The point 6 on the crank circle is the crank position when **top compression begins**. With a straight line connect points N and P and, with O as a center,

Valve Load. A number of formulas are in use for obtaining the loads on the valves in order to proportion bearing surfaces and the strength of the various parts of the valve gear. Some formulas take into account the weight and inertia of the valve gear and others the friction of the valves. Any formula must be more or less empirical, and it is well to simplify the calculation by basing the load on the friction of the valves only and keeping the pressures and stresses low enough to cover all other contingencies. The pressures and stresses mentioned under valve gear details have been found by

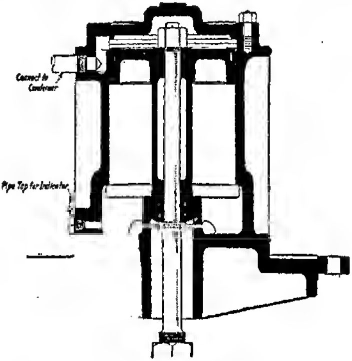

FIG. 85.—Lovekin assistant cylinder.

successful practice to be satisfactory and are based on valve loads found by the following formulas:

$$\text{Valve load in lb} = L = c \times b \times l \times p \text{ for slide valves}$$
$$= c \times \pi d \times l_1 \times p \text{ for piston valves}$$

where c = coefficient of friction
b and l = width and length of slide valve
d and l_1 = outside diameter and length of top + bottom piston valve rings
p = unbalanced absolute pressure between the steam and exhaust sides of the valve

The constant c should be taken 0.15 for intermediate-pressure and low-pressure slide valves and 0.22 for high-pressure and intermediate-pressure piston valves which values are high enough to cover almost dry surfaces, a condition which is liable to occur. For low-pressure cylinders, p should be taken not less than 30 lb for compound, 25 lb for triple, and 20 lb for quad-

draw a circle tangent to NP. The radius OR of this circle is the exhaust lap. If this circle lies within circle HO, the lap is negative and, if within circle OJ, the lap is positive. When the width of the port is less than HL, an arc XYZ is drawn making the distance YL equal to the port opening. The steam lap, lead, release, and valve travel must be adjusted until considered satisfactory for the required cutoff. The diagram is always laid off in the same manner relative to the top of the stroke whether the valve takes steam inside or outside. A separate diagram must be drawn for each cylinder. To

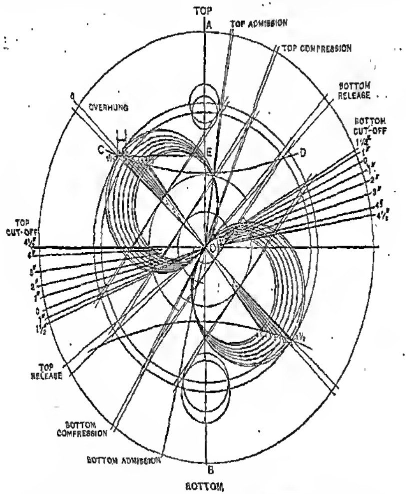

FIG. 75.—Zeuner valve diagram for crossed eccentric rods.

find the valve functions for linked up positions, see Fig. 74, which is a complete diagram for open rods. The arc CD is described through point C from a center on OB extended and with a radius equal to

$$\frac{\text{Length of eccentric rod} \times 2 \times EC \text{ (Fig. 74)}}{2 \times \text{distance between eccentric rod pins on link}}$$

Considering the length of the arc CD as equivalent to the length of the link, lay off proportionally from E the points 1, 2, 3, etc., to represent linking up of 1, 2, 3, etc., in., and describe circles with $O1$, $O2$, $O3$, etc., as diameters. From these circles the points of admission, cutoff, release, and compression,

ruple engines; for other cylinders p may be taken from Table 2. For slide valves the total area of the back of the valve is used, neglecting the effect of the relief ring, if any, as the valve gear must be proportioned to operate the valve should the relief ring fail to work. The load for piston valves depends on the fit of the valve rings. With tight rings and dry surfaces the load may exceed that given by the formula. The valve loads for all cylinders should be determined and, unless the loads are materially different, the valve gear proportioned from the largest load and the parts made the same throughout the engine. Often, however, the valve load for the low-pressure cylinder is much greater than for the other cylinders, and it is not unusual to increase the size of the parts for this cylinder, The following details of valve gear cover Stephenson link motion, but the details of other types may be designed in the same manner by using the valve load L as a basis.

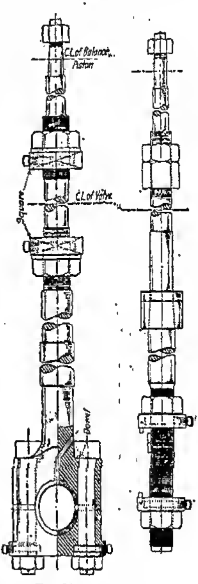

FIG. 86. FIG. 87.
Valve stems.

Valve Stems. When one valve is used, the valve stem is fitted with a **cap and adjustable brass bushing** at the lower end (Fig. 86) which attaches to the link block. When there are two valves, the stem (Fig. 87) is **screwed into a crosshead**, which connects to the link block. Piston valves are secured to the stem by a collar and washer below and lock nuts above the valve. **Adjustment of the valve along the stem** is made by changing the thickness of the washer. **To provide for wear** of a slide valve and to allow the steam pressure to hold it firmly against its seat, the hole through which the stem passes is made oval. Nuts above and below the valve are locked against a pipe distance piece over the stem or in some other manner so that the valve is free on the stem. The diameter of the valve stem below the valve is determined by the method given under Piston Rods, p. 1092, using the valve load L and a factor of safety of about 30. The stress at the bottom of the thread in the valve should not exceed 3,000 lb. The cap and bolts are proportioned in a manner similar to connecting rod caps and bolts using the same allowable stresses. The stems, collars, nuts, caps, and bolts are forged steel.

Valve-stem Crossheads. When two piston valves are used a crosshead, usually of cast steel, of a design similar to Fig. 89 is used. The lower end of the crosshead carries the bushing for attaching to the link block.

corresponding to the linked-up positions, may be found in the same manner as for full-gear condition first described. **For crossed rods** the arc CD is laid off from a center on OA extended instead of on OB as shown in Fig. 75 which is a complete diagram for crossed rods.

In some cases the links are arranged for carrying the cutoff beyond the point of attachment of the eccentric rods thus increasing the valve travel and decreasing the angle of advance; this may be represented on the diagram by a proportionate extension of the equivalent link line CD (Fig. 75) beyond the point C and is generally called **overhung gear.** The difference between open and crossed rods can best be understood by comparing the valve functions for different cutoffs as shown by the curves in Fig. 67, which are drawn for valve gears with open and crossed rods suitable for the same engine. For crossed rods in this case it was found advisable to overhang the links $1\frac{1}{4}$ in. to get the benefit of larger valve travel and the proper range of cutoff without reducing too much the steam opening and steam lead when **linked up.** The large steam opening and steam lead at maximum linked-out position necessary to obtain good running conditions in the maximum linked-up position may be noted.

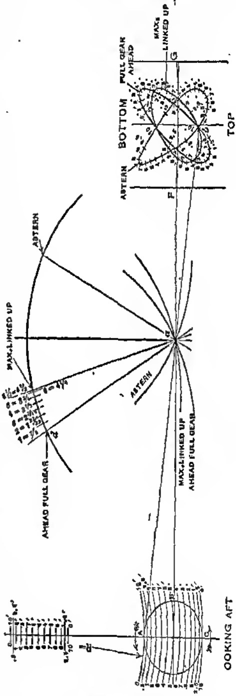

FIG. 76.—Construction of oval-valve diagram for Marshall gear.

The oval-valve diagram is frequently used in connection with radial valve gears. Its construction for Marshall valve gear is as follows:

The path of the lower valve rod pin b, during one revolution, is plotted by laying off to a convenient scale or by use of a simple model, the locations of the

Valve-stem Guides. The valve stem must be guided at the lower end to prevent the side strain due to the angularity of the eccentric rods or the action of the links, from bending the stem or throwing a pressure on the stuffing box. For a **single valve** this guide may be a separate casting or cast with the lower valve chest cover as shown in Fig. 88. The bearing surface will be ample if the diameter in the guide is made ¼ to ½ in. more than the diameter of the stem and the length 3 times the diameter. The guide is lined with brass and fitted with a removable cap. **When a crosshead is used,** the guide is cast iron or steel as shown in Fig. 89 with adjustable brass gibs fitted in the crosshead. As one valve is liable to work much stiffer than the other and throw continual pressure on the guides, it is advisable to make the bearing surface almost double that used for a single valve. The upper end of the valve stem is guided by the balance piston or by a bronze bushing in a cast-iron hood.

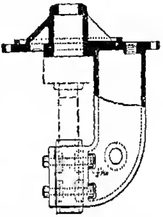

Fig. 88.—Valve-stem guide.

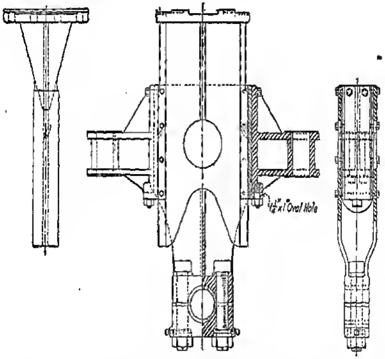

Fig. 89.—Valve-stem crosshead and guide.

Links. The double-bar type (Fig. 90) is generally used. The mean radius is the distance between the center of the eccentric and the center of the link. The links are forged steel machined all over and held together at the ends by bolts through cast-iron distance pieces. The four forged-steel eccen-

centers of the eccentric rod, the suspension pin d on the bell crank and the attachment of the swinging link B to the eccentric rod at a, Fig. 69. On the eccentric circle ABC (Fig. 76) with a radius =

$$\frac{2 \times \text{eccentric} \times \text{length of connecting rod}}{\text{stroke}},$$

arcs are drawn corresponding to each tenth position of the piston. The intersections of these arcs with the eccentric circle marked 1, 2, 3, etc., for the down stroke and 1′, 2′, 3′, etc., for the upstroke, are used in plotting the path of the lower valve rod pin, which is done for full gear ahead, maximum linked up, and astern positions as shown. Points on the path of the valve rod pin are marked to correspond to the piston positions. In Fig. 77, draw line DE representing the stroke of the piston to a convenient scale and divide into tenths. On the left side of line DE plot the positions of the valve for the down stroke of the piston which are found by scaling off the vertical distances of the points on the path of the valve rod pin from the arc FG, the radius of which is the length of the valve rod. On the right side of DE plot the positions for the up stroke. A line through these points will describe an oval figure representing the positions of the valve for the corresponding positions of the piston. Draw the different lap lines for steam and exhaust parallel to DE, the left side representing the down stroke and the right side the up stroke. The intersections of the lap lines and the oval represent the **points of admission, cutoff, exhaust release, and compression.** If the exhaust lap is positive, the lap line is drawn on the opposite side of its steam lap and, if negative, on the same side. In the diagram shown in Fig. 77, the top exhaust lap is zero. A separate diagram must be drawn for each cylinder. The diagram shows that increasing the steam lap decreases the lead and the cutoff, and increasing the exhaust lap makes release later and compression earlier. Owing to the angularity of the connecting rod and the curvature of the path of the point a, Fig. 69, the oval is not a true ellipse but one end is fuller than the other which shows that the top and bottom cutoffs are unequal. To partly overcome this the laps are made unequal. As lead is constant for all grades of expansions ovals drawn for linked-up positions will all pass through the same top and bottom points of lead.

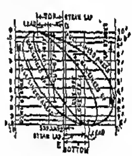

FIG. 77.—Oval-valve diagram for Marshall gear.

Valve Diagram Data. When the valve diagrams have been drawn for each cylinder the data are tabulated on the drawing for easy reference as shown in Table 16. It is also well to plot on the drawing, curves similar to Fig. 78 showing the changes in the valve functions for different link positions so that the cutoff, release, compression, etc., may be easily read for any position of the links. Table 16 and Fig. 78 are from the valve diagram of an actual engine.

Flat Slide Valves. On cylinders in which the pressure will not cause excessive wear, it is customary to use a slide valve. If the cylinder is large, this valve may be double-ported as shown in Fig. 79 or even triple-ported to reduce the travel and to give quick-closing ports. The faces of the valve and seat are sometimes scraped to a true surface but usually, if these faces are

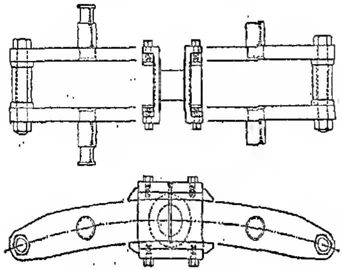

FIG. 90.—Links and link block.

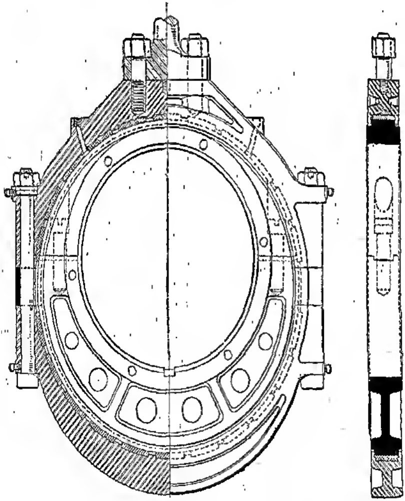

FIG. 91.—Eccentric and eccentric straps.

planed at right angles, they will soon wear to a good surface. To reduce friction, grooves are often cut in the bearing surface of the valve or seat so steam may enter and act as a lubricant. Care must be taken that the valve has sufficient bearing surface in order to keep the pressure per square inch within proper limits. If the ports are very wide, one or more central bars must be used. Even though the pressure per square inch on a slide valve may

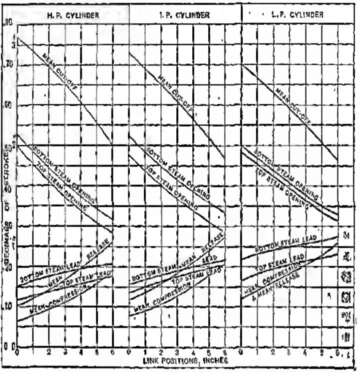

Fig. 78.—Changes in valve functions for different link positions.

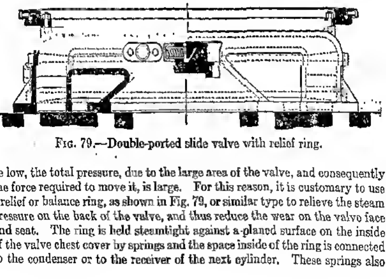

Fig. 79.—Double-ported slide valve with relief ring.

be low, the total pressure, due to the large area of the valve, and consequently the force required to move it, is large. For this reason, it is customary to use a relief or balance ring, as shown in Fig. 79, or similar type to relieve the steam pressure on the back of the valve, and thus reduce the wear on the valve face and seat. The ring is held steamtight against a planed surface on the inside of the valve chest cover by springs and the space inside of the ring is connected to the condenser or to the receiver of the next cylinder. These springs also

tric rod pins, two of which are extended to form the suspension rod pins, are riveted through the link bars. The suspension rods, for merchant engines, are generally attached to the go-ahead eccentric rod pins to reduce the slotting action of the link block in ahead gear. The **depth of the bars** is made about three times the thickness and the **distance between eccentric rod pins** six to seven times the eccentricity. The **eccentric rod pins are proportioned** for a bearing pressure of 600 to 800 psi. The **area of the suspension rod pins** is about three-fourths that of the eccentric rod pins. Each **link bar is proportioned** as a beam, supported at the eccentric rod pins, to carry half the valve load, L, in the middle; 5,000 to 5,000 lb stress may be allowed.

Link Blocks. Figure 90 shows a forged-steel link block of the usual type. The pin for the attachment of the valve stem is proportioned to carry the valve load with a pressure of 600 to 950 psi. The **length** is made equal to the diameter. Brass faces or gibs, proportioned for a pressure of 250 to 350 psi, are fitted between the link block and the links.

Eccentric Rods. The **diameter** of the eccentric rod is determined in the same manner as a connecting rod using hinged ends, the valve load, L, a length equal to the distance between the centers of the eccentric strap and the pins on the links, and a factor of safety of 18 to 22. The **diameter of the lower end** is made about 1.3 times that of the upper end. The rods are forged steel fitted at the upper end with adjustable brass bushings secured by a forged steel or brass cap. The fork of the ahead rod is usually made symmetrical and the astern rod offset (see Fig. 107). The **fork should be proportioned** as explained under connecting rods, allowing a stress of about 4,000 lb. The lower end of the rod is secured to the eccentric strap by two bolts which must be proportioned to carry the valve load. The length of the eccentric rod varies from 8 to 15 times the valve travel.

Eccentrics. The usual type of eccentric (Fig. 91) is of cast iron although the smaller part is sometimes forged or cast steel. The parts are held together by bolts about 1 in. for a 12-in. to 2-in. for a 80-in. eccentric. The keyway, which is always in the large part, is often made wider than the key and side keys fitted so that small changes in the angle of advance may be made. **To secure the eccentric against moving sideways** a setscrew is fitted, or the ahead and astern eccentrics are bolted together. The joint between the parts is stepped to take side strain off the bolts. The **width of the eccentric** is determined from the valve load, L, the projected area being such that the pressure per square inch is 60 to 140 lb.

Eccentric Straps. Figure 91 shows a cast-steel eccentric strap lined with white metal of the type generally used. A lip at each side of the bearing surface keeps the strap in place. The **strap should be sufficiently stiff** not to pull away from the eccentric where bolted to the rod or cause excessive friction by closing in at the sides. The bolts connecting the top and bottom must safely carry the load on the valve gear. As spare eccentric straps are usually carried, the top and bottom parts are often made from the same pattern to reduce the number of spare parts (see Fig. 107). The lower part of the strap is proportioned by considering it as a beam supported at the centers of the bolts and loaded in the middle with the valve load, L, allowing a stress of not over 4,000 lb for cast steel.

Reversing Gear

For small engines reversing is accomplished by a hand lever attached directly to the reverse shaft or by some hand-operated gear, either worm and

wheel, or screw. For large engines, steam reversing gear is fitted. The "all-round" type is almost universally used in European practice, and the "direct-acting" type in American practice.

The all-round type (Fig. 92) consists of a small one- or two-cylinder engine driving a worm and worm wheel. The worm wheel is connected

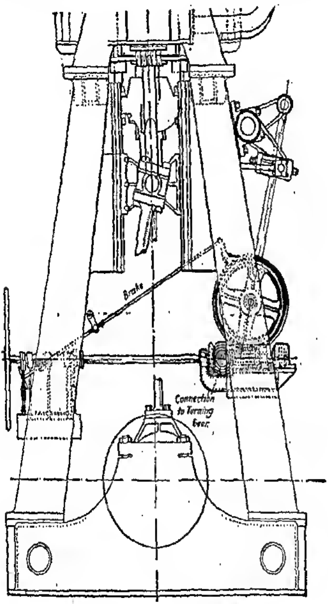

FIG. 92.—All-round reversing gear.

to an arm on the reverse shaft by a connecting rod and a crankshaft or a connecting rod and a pin in the rim of the wheel. The engine is usually fitted with a flywheel of large diameter with a light smooth rim readily accessible for use as a handwheel for starting the reversing engine when on dead center, or in making slight movements of the valves. The flywheel also forms an emergency means of starting the valve gear in case it should

serve to reseat the valve in case it is lifted off its seat by water in the cylinder or any other cause.

Slide-valve False Face. A hard close-grained cast-iron false face or liner is generally fitted to the cylinder as a working surface for a slide valve, as shown in Fig. 80. This liner varies from about 1 to 2 in. thick depending on the size of the engine and is firmly secured to the cylinder by a number of bronze screws set about ⅛ in. below the surface to allow for wear.

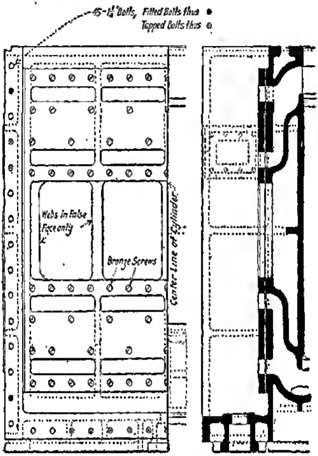

Fig. 80.—Slide-valve false face.

Piston Valves. It is customary to use a piston valve on the high-pressure cylinder as the wear of a slide valve is excessive under high pressure. The volumetric clearance is more than with a slide valve, owing to the steam passages extending around the valve but the use of straight ports reduces this difference. A piston valve, if properly fitted, works with little friction but is not as steamtight as a slide valve and, as it cannot lift from its seat if dirt or an obstruction enters the port, it is liable to stick and throw severe strains on the valve gear. For the same reason water in the cylinder is unable to escape. Piston valves take **inside steam** when the steam enters the cylinder past the inner edges of the valve rings and **outside steam** when the steam

stick. The all-round type of gear is also useful in warming-up as the reversing engine may be kept running and continuously reversing the valves. It is less liable to be damaged by careless handling, and the engine may also be arranged to operate the turning gear. The valve gear for the reversing engine is sometimes fitted with a "follow-up" gear which stops the reversing engine when the gear of the main engine has reached the desired position. An indicator is usually fitted so that the valve position may be readily seen. Sometimes a brake is fitted so that the engine may be stopped quickly and held at any point.

The "direct-acting" type (Figs. 93 and 106) consists of a cylinder with a connecting rod directly connected to the reverse shaft arm, one stroke of the piston moving the reverse shaft from ahead to astern position. The valve gear of this engine is operated by a hand lever fitted with a quadrant for securing it. A follow-up gear stops the reversing engine when the gear of the main engine has reached the desired position. The piston should be provided with stops at each end of the stroke consisting of springs or of bosses on the piston which strike the cylinder head. The valve of the reversing engine is usually of the *D* slide type. A V-notch is often cut in the steam lap at each end of the valve (Fig. 93) which makes the steam balance maintained by the follow-up gear more sensitive and the movement of the piston more easily controlled by slight movements of the valve. To provide a cushioning effect, the reversing gear of a large installation sometimes has an oil or water cylinder in tandem with the steam cylinder with a valve also in tandem, so that any movement of the steam valve and piston causes a corresponding movement of the hydraulic valve and piston allowing the fluid to flow from one end of the hydraulic cylinder to the other. The fluid may be throttled, so as to regulate the speed of the movement. Sometimes the hydraulic cylinder is also fitted with an auxiliary hand pump which may be used as a hand reversing gear or as an emergency gear in case the main engine valve gear sticks.

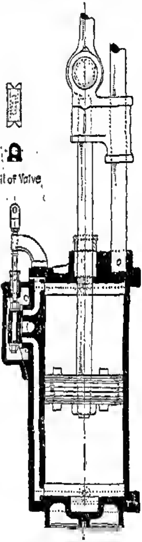

FIG. 93.—Direct-acting reversing engine.

The size of reversing engine is determined more or less empirically but, with constants taken from practice, the following formula, adapted from Bauer, gives good results:

$$d_s^2 = \frac{1 \times t}{p \times n} \times c$$

enters past the outer edges. The general type of piston valve is shown in Fig. 81. Large piston valves are often made with cast-steel ends riveted to a central section of steel tubing, as shown in Fig. 82. The rings are sometimes held against the valve liner by springs but, on account of excessive wear, it is better to use solid rings or, to provide for adjustment, to have the rings cut and the ends fastened together by screws or bolts as shown in Fig. 82. The diameter of the rings may then be increased by the use of liners. On intermediate-pressure cylinders, either piston or slide valves are used, according to the idea of the designer. To avoid excessive distances from the center of the cylinder, two piston valves may be used instead of one as discussed on p. 1153.

Piston Valve Liners. A hard close-grained cast-iron liner is usually fitted in the valve chest as a working surface for a piston valve as shown in Fig. 81. The thickness varies from about ⅞ to 1¼ in., depending on the size of the engine. The bridges in the steam port (see Fig. 81) are arranged diagonally to ensure equal wear on the valve rings and are usually about 25 per cent of the circumference of the valve. The openings in the valve liners are accurately machined. The ends of the liners are counterbored to allow the valve rings to overrun a short distance at each end.

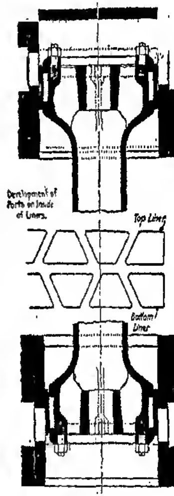

FIG. 81.—Cast-iron piston valve.

Expansion Valves. With the ordinary types of valve gear and the usual valve laps a variation of cutoff of 15 to 25 per cent may be obtained. If a greater range or an earlier cutoff is desired, a separate expansion or cutoff valve, consisting of an auxiliary valve, working on top of or within the main valve and driven by a separate eccentric, is fitted. This valve is arranged so that the cutoff desired may be obtained by changing its position by means of a screw. To obtain a wide range the main valve is usually designed for a very late cutoff so the auxiliary valve can effect only an earlier cutoff. The other functions of the main valve are not changed. Although seldom fitted at the present time, there is a large number of engines with these valves still in service.

Trick Valves. To obtain a quicker and fuller opening of the steam port, trick valves are sometimes used. Figure 83 shows a trick slide valve and Fig. 84 a trick piston valve. Passages are cored through the valve and so arranged that their entrances just overlap the end of the valve seat or liner when the valve is at the end of its stroke. As the valve uncovers the steam port at one end, the cored passages admit steam to the same port from the other end of the valve. The width of the trick ports is such that they are completely open to steam at the same time as the steam port. Exhaust takes place only through the inner passage of the main valve in the same manner as valves of the ordinary type. The valve diagram for a trick valve is drawn in the same manner as for an ordinary valve keeping in mind that the steam opening is the sum of the openings of the main and the trick valves.

where d and s = diam. and stroke of reversing engine
l = maximum load on one main engine valve (see Valve Load)
t = half travel of the valves
p = boiler press. (gage)
n = revolutions of reversing engine required to reverse main engine (= 1 for direct-acting type)
c = constant

All dimensions are in inches. If a double-cylinder all-round engine is used, d^2 is the sum of the squares of the two cylinders. For three-cylinder triple-expansion engines with cranks at 120 deg, Bauer's values of c, modified to agree with the above formula, are 7 for direct-acting, and 17 for all-round type; and for four-cylinder triple- and quadruple-expansion engines with cranks at 90 deg, 10 for direct-acting, and 23 for all-round type. However, reversing engines are often made of such size that the constants are from 1½ to 2 times these values.

For the direct-acting type the diameter of the reversing cylinder may be taken roughly as 0.15 to 0.23 times the diameter of the low-pressure cylinder for all types of engines and the stroke 2 to 3 times the valve travel. For the all-round type it is usual to make the stroke about equal to the cylinder diameter.

Reversing Gear Load. The various parts of the reversing gear are proportioned from the **reversing-engine load, $P = Ap$,** where A = area of reversing-engine cylinder and p = steam pressure, which for purpose of design is taken as boiler press. As this maximum load comes on the gear only in case the valves stick, stresses figured by this method may run much higher than ordinary working stresses. For simplicity and in view of the margin of safety in using boiler press, the angularity of the reversing-engine connecting rod and the suspension rods is neglected.

Reversing-engine Piston Rod, Connecting Rod, and Crosshead. The piston rod is forged steel tapered at each end and secured to the piston and the crosshead by nuts. The **crosshead** (Fig. 106) is of cast steel or composition and carries the forged-steel connecting rod pin and the crosshead guide shoe which is composition bushed if the crosshead is of steel. The **connecting rod** (Fig. 106) is a steel forging with a solid brass bushing at the crosshead end and a split brass bushing with steel cap at the other end. The piston rod and connecting rod are proportioned by the method given under main engine piston and connecting rods, using a factor of safety of 8 to 10. The direct tension in the piston rod at the base of the threads may run as high as 10,000 lb. The stress in the crosshead pin is figured in the same manner as a main crosshead pin of the same type, a stress of about 5,000 lb being allowable. The bearing pressure on the crosshead pin may be as high as 3,500 psi. The **length of the connecting rod** is usually about 1½ to 2 times the stroke of the reversing engine.

Reverse Shaft. The reverse shaft (Fig. 106) is forged steel and supported by bearings bolted to the engine housings or to the cylinders. The stress in the shaft is figured from the equivalent twisting moment. Usually at one or both ends of the shaft a reversing arm is located outside of the bearing, so that it is overhung. The **reversing-engine arm** should be located near the middle of the shaft to keep torsional stresses low, and near a bearing to reduce bending. The equivalent twisting moment is figured at each reversing arm to determine the maximum value between bearings and overhung. The stresses are then found by dividing the largest equivalent twisting moment

Balance Cylinders and Pistons. To relieve the eccentrics of a large portion of their load, a balance cylinder with its piston attached to an extension of the valve stem is often fitted in the upper valve chest cover of heavy piston or flat slide valves as shown in Figs. 106 and 107. The underside of the piston is in communication with the valve chest or receiver and the upper side connected to the condenser or a steam chest of lower pressure.

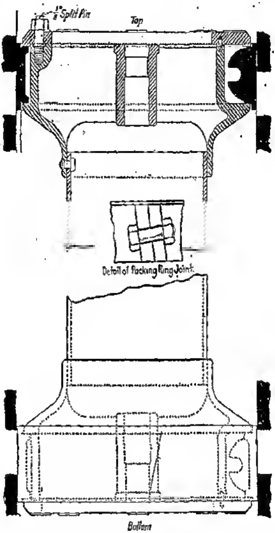

Fig. 82.—Steel-piston valve.

The area of the piston is made such as to just support the weight of the valve and gear so that the valve load is made up entirely of friction. In case of the low-pressure valve, where the low steam pressure in the chest would necessitate a very large balance piston, the underside of the piston is sometimes connected to the intermediate-pressure instead of to the low-pressure chest or receiver. The pistons are solid cast iron packed with several small cast-iron rings. The balance piston acts as a guide for the upper end of the valve stem.

for each condition by the resistance. If T = twisting moment and B = bending moment, the equivalent twisting moment $= B + B\sqrt{1 + (T \div B)^2}$. The resistance to twisting $= D^3/5.1$ where D is the shaft diameter. The maximum twisting moment occurs at the reversing-engine arm, and $= P \times L$, where L = length of the arm. Usually the maximum equivalent twisting moment between bearings will be at the reversing-engine arm. If there is also a reversing arm between the same bearings, the bending moment used is the resultant of the components of the bending moments. For reversing arms at the ends of the shaft, the twisting moment is the product of the load on the reversing arm times the length of the arm. For reversing arms between the ends and the reversing-engine arm, the twisting moment will be the sum of the twisting moments of all the arms between the end of the shaft

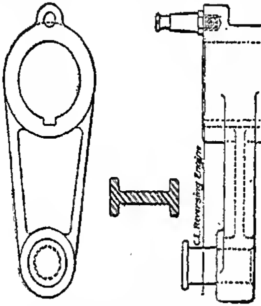

Fig. 94.—Reversing-engine arm.

and that point. Stresses in reverse shafts figured by this method may safely run from 8,000 to 10,000 lb.

The **reversing-engine arm** (Fig. 94), usually of cast steel of I section, is figured for bending stress near the hub due to the reversing-engine load P. If b = distance from center of the pin to the section taken and R = resistance of the section, stress $= \frac{P \times b}{R}$. This stress may safely be 10,000 lb. The pin in the reversing-engine arm is proportioned for a bearing pressure of about 3,000 lb due to the load P, and also for bending stress. If l = length of pin and d = diameter in the arm, stress $= \frac{P \times l \times 10.2}{2 \times d^3}$. The allowable stress may run as high as 18,000 lb. Diameter of reversing-engine arm boss = 1.6 times diameter of the shaft and the length equal to shaft diameter. The lengths of the reversing-engine arm and the reversing arms are proportioned approximately so that

To Multiply 4 by 6. In Fig. 1, starting with point 1 of the fixed scale, run the eye along from 1 to 4; then set the 1 of the slide opposite this point 4, and *run the eye forward along the slide from* 1 *to* 6; the point thus reached on the fixed scale is 24, which is equal to 4 × 6. This process gives the distance from 1 to 4 *plus* the distance from 1 to 6, and is, in fact, a mechanical method of adding the logarithms of these numbers; hence the result is the product of the numbers. Conversely,

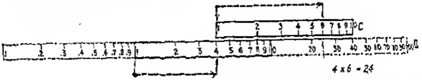

Fig. 1.

To Divide 4 by 6. In Fig. 2, starting with the point 1 of the fixed scale, run the eye along from 1 to 4; then set the 6 of the slide opposite the point 4, and *run the eye backward along the slide from* 6 *to* 1; the point thus reached on the fixed scale is 0.667, which is equal to 4 ÷ 6. This process gives the distance from 1 to 4 *minus* the distance from 1 to 6; and is, in fact, a mechanical method of subtracting the logarithms of these numbers; hence the result is their quotient.

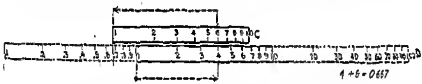

Fig. 2.

Multiplication and Division, Using Only a Single Section of the Scale. If only the main section of scale *D* is available (as is usually the case in practice), the result of multiplication may fall beyond the scale, as it does in Fig. 1. In such cases *divide the first factor by* 10 *before beginning to multiply;* this will bring the result within the scale, without affecting the sequence of digits.

For example, to multiply 4 by 6. Having found that the setting shown in Fig. 1 is not successful, *reset the slide as in Fig.* 3, *with* 10 *instead of* 1 *opposite* 4; run the eye backward along the slide from 10 to 1, thus reaching the (unrecorded) point corresponding to 4 ÷ 10; then, continuing from this point, run the eye forward along the slide from 1 to 6, as before; the point finally reached on the main scale is 2.4, which has the same sequence of digits as the required value 24. After a little practice, this preliminary step of dividing by 10 will be performed almost intuitively. Whether or not this step is necessary in any given case can be determined only by trial.

The **general rule for multiplication** may be stated as follows, if preferred: To find the product of two factors, find one factor on the fixed scale; opposite this, set (tentatively) point 1 of the slide; on the slide find the second factor, and opposite this read the product on the main scale, if possible. If the product falls beyond the scale, begin over again, using point 10 of the slide instead of point 1.

In division also, the result may fall beyond the main section of the scale, as it does in Fig. 2. In such cases, it suffices merely to *multiply the result by* 10 in order to bring it within the scale; this will not affect the sequence of digits.

For example, to divide 4 by 6, set the slide as in Fig. 4, and follow out mentally the steps indicated by the arrows. It will be noticed that the supplementary step of multiplying by 10 is performed by simply running the eye along the slide from 1 to 10 without resetting the slide; for this reason, division on the slide rule is slightly easier than multiplication.

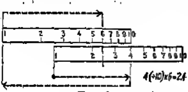

FIG. 3.

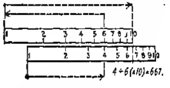

FIG. 4.

The Ordinary Mannheim Slide Rule has four scales, A, B, C, D, as shown in Fig. 5. Scales C and D are essentially the same as the C and D scales described above, and the principle just explained shows how they are used in multiplication and division. The fact that the D scale covers only the main section from 1 to 10 (all decimal points being omitted) is practically no restriction on the scope of the scale, as is seen in the preceding examples. A runner is provided, so that intermediate positions reached in the course of an extended computation may be indicated temporarily on the scale without the necessity of reading off their numerical values. The best runners are those which have no side frame to obscure the numerals.

FIG. 5.

In problems involving successive multiplications and divisions, arrange the work so that multiplication and division are performed alternately.

For example, to calculate $\dfrac{a \times b \times c}{d \times e}$, divide the product $a \times b$ by d; multiply this quotient by c; and divide this product by e. Each operation will require only one shifting either of the slide (for multiplication) or of the runner (for division).

To multiply a number of different quantities by a *constant multiplier* x, set the point 1 of slide opposite x, and read, by aid of the runner, the products of x by all the quantities which do not fall beyond the scale; then reset the slide, setting 10 instead of 1 opposite x, and read the products of x by all the remaining quantities.

To divide a number of different quantities by a *constant divisor* y, first find (by the slide rule) the quotient $1 \div y$, and then use this as a constant multiplier.

Scales A and B are exactly like scales C and D, except that they cover two sections of the complete logarithmic scale, the graduations being only half as fine. Either pair of scales may be used for multiplication and division; C and D give more accurate readings, but have the disadvantage that in the case of multiplication the slide must often be shifted to the other end in order to keep the result on the scale—an inconvenience which is not present when the less accurate scales A and B are employed.

By the use of both pairs of scales, problems in squares and square roots may be readily solved; for every number on A, except for the decimal point, is the square of the number directly below it on D (use the runner).

$$\frac{\text{Distance bet. ecc. rod pins on links}}{\text{Length of reversing arm}} = \frac{\text{length of reversing arm}}{\text{length of reversing-engine arm}}$$

The follow-up gear of the reversing engine is often attached to a pin in the boss of the reversing engine arm, as shown in Fig. 94.

The **reversing arms** (Fig. 95) are usually of cast steel of I section and should be placed near a bearing to reduce bending moments in the shaft. Each reversing arm is fitted with a screw working in a crosshead having a pin at each end, to which the suspension rods are attached so that the linkage of any cylinder may be varied by adjusting the screw. **The slot in the reversing arm** should be approximately parallel with the suspension rods in ahead gear and perpendicular to them in astern gear so that linking up has no effect when going astern. The reversing arms are also figured for bending stress near the hub. Let Q = the load on the arm, b_1 = distance from center of crosshead to the section taken, and R_1 = resistance of the section. As the reversing arms for all cylinders are usually made the same, R_1 and b_1 will be

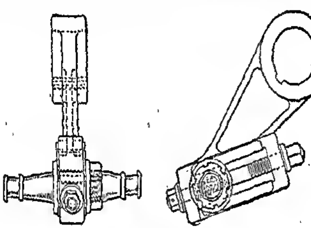

Fig. 95.—Reversing arm.

the same for all cylinders, but Q will vary in proportion to the valve loads. If L = length of reversing-engine arm from center of pin to center of shaft, L_1 = corresponding length of the reversing arm, then the **total load on all reversing arms**, $P_1 = P \times \frac{L}{L_1}$. The load P_1 is divided among the reversing arms in proportion to the valve loads, *i.e.*, the load Q on any reversing arm is equal to $P_1 \times$ the ratio of the valve load for that cylinder to the sum of the valve loads. Stresses may safely run as high as 10,000 lb. The diameter of the reversing arm boss = 1.6 times and the length 0.8 times diameter of shaft. The adjusting screw is figured for direct tension at the bottom of the threads, the load being Q and the allowable stress about 5,000 lb.

The **reversing-arm crosshead** (Fig. 95) is figured for bending stress in a section through the middle, through which the adjusting screw passes. If L' = distance between centers of suspension rod pins, B = width and D = depth of middle section, and d = diameter of hole for the adjusting screw, stress $= \frac{Q \times L \times 6}{4 \times D^2(B - d)}$ which may run to 6,000 lb. The crosshead is also figured as a cantilever at the collar, where the tapered portion joins the central

has returned to normal, the pivoted weight is returned to its original position by the springs, and the detent, D, alters the position of the pawls, PP, so that the upper pawl picks up the lever, H, and opens the throttle. Should the speed continue excessive the repeated movement of the weight causes the first pawl to remain set, and the throttle remains closed until the speed has become normal. This governor is also fitted with an emergency weight, A, which comes into use in the case of very excessive speed such as would result from losing a propeller or breaking a shaft. The action of the weight, A, causes the weight, W, to be locked which results in the throttle remaining shut until the engine stops and the throttle can be unlocked. This governor may be arranged to operate the reversing gear instead of the throttle.

Handling Gear. All gear necessary for the control and maneuvering of the engine should be located at one point and arranged for quick and easy handling under emergency conditions. The levers for operating the throttle, butterfly valve, and reversing engine are usually located together on a bracket

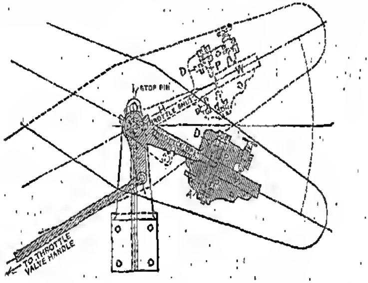

FIG. 105.—Aspinall governor.

fitted to the side of the forward or second housing at a convenient height from the engine-room floor. The receiver-steam and cylinder-drain controls are located on the same side of the engine as the throttle control but not necessarily at the same point. The butterfly valve, used for quick control of the engine when racing due to pitching of the vessel in a heavy sea, is also connected to the governor, if fitted, for automatic control under such conditions. The various water-service and lubricating-oil cocks are placed where most convenient.

Working Platform and Gratings. The engine controls are handled from the engine-room floor, but gratings should be placed wherever necessary to provide access for oiling, indicating, and making repairs on the main engine as well as for access to other equipment about the engine room. The usual arrangement consists of a grating all around the engine below the bottom of the cylinders with cross gratings between the housings for access to the crossheads and stuffing boxes. Another grating is fitted all around the engine near the top of the cylinders for use when indicating or making repairs on cylinders or pistons.

block. This section is usually circular and, if l = distance from center of pin to section taken and d = diameter of section, stress $= \frac{Q \times l \times 10.2}{2 \times d^3}$. This stress is usually higher than the stress in the central block, and runs about 8,000 lb. The pins are proportioned for a bearing pressure of about 1,000 lb.

The **suspension rod** (Fig. 96) is figured as a column with hinged ends, loaded with half the reversing-arm load. The lowest factor of safety is usually in the low-pressure rods and runs about 30 to 40. The caps and bolts are figured in the usual manner.

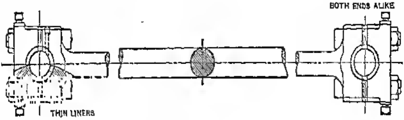

FIG. 96.—Suspension rod.

Turning Gear

Provision is always made for turning the engine for the purpose of setting the valves, making repairs, or for keeping the bearings and working parts in condition when in port by turning the engine several revolutions when considered necessary. A simple form of turning gear used on **small engines** consists of recesses in the coupling, or a notched wheel attached to the shaft to which a bar or jack may be applied. For **larger engines,** a worm wheel is fitted on the shaft or coupling and operated by a worm which may be disengaged by having the worm shaft pivoted or the worm working on a feather on the shaft thus allowing it to be moved axially out of gear when the turning gear is not in use. This worm is usually actuated by a small single- or double-cylinder engine although a ratchet lever is often used on engines of small size. If hand operation is used, the ratio of revolutions of the worm to the revolutions of the engine is about 50:1. If an engine is used, a second worm and wheel are introduced, making the ratio of gearing such that the revolutions of the turning engine required for one revolution of the main engine is from 1,200:2,000 or even more for very large engines. The turning engine operates at 200 to 400 rpm and it required 5 to 8 min to turn the main engine one revolution. The engine should be of sufficient size to turn over the main engine in port with steam pressure of 80 lb or less. A flywheel is usually fitted and the engine has a change valve, links, or shifting eccentric for reversing so the main engine may be turned in either direction. Holes in the rim of the flywheel for inserting a bar provide means for turning the engine by hand. The engine is generally located on the engine housing or bedplate, a typical arrangement being shown in Fig. 97. If an all-round reversing engine is used, it is generally also arranged for turning through a belt, chain, or shafting and a separate engine is not required.

The following formula, adapted from Bragg, may be used for determining the size of **turning engine**: $d^2s = \frac{D^2 \times S}{R} \times C$ where d and s = diameter and stroke of turning engine D and S = diameter of low-pressure cylinder

Lubrication. Merchant engines are fitted with gravity lubrication to all bearings, crosshead guides, and thrust and line-shaft bearings. Oil cups or boxes may be fitted directly on the part to be lubricated, but it is usual to provide a box or reservoir, of a capacity to last several hours, on the side of each cylinder from which pipes are led to the cups or boxes on the engine. These boxes or reservoirs have small tubes fitted with wicks leading up through the oil, which by capillary attraction and siphon effect feed the oil through a sight feed to the point to be lubricated. The size and number of wicks control the flow. Receptacles mounted on rapidly moving parts into which oil is dropped from the distributing system should be packed with curled hair held in place by a perforated cover or wires to prevent the oil being thrown out and to keep dirt from plugging the pipes. An oil box is mounted on each main bearing cap with one or more tubes feeding the bearing. A cup is fitted on each eccentric rod with a pipe leading down to the eccentric strap. For all valve gear, air pump, and reversing- and turning-engine parts, where the movement is intermittent, an oil cup of commercial make is usually fitted. The crosshead guides have oil piped to both the forward and after sides and lead by suitable drillings to the face of the guide, on which are oil-retaining grooves. At each stroke a wiper on the crosshead dips into a box fitted at the bottom of the guide and distributes on the face of the guide the oil that runs down into the cup. Oil boxes on top of the crosshead pin caps, lubricate the crosshead pins through drillings in the caps. The same boxes lubricate the crankpin through one or two pipes lead down the connecting rod. The thrust bearing is lubricated by a cup with capillary feeders on each shoe with oil channels lead to the face of each collar. The base of the thrust bearing is usually filled with oil in which the lower part of the collars is immersed. The line-shaft bearings are lubricated either by oil cups with capillary feeders mounted on the caps or by a block of grease placed in an opening in the cap which lubricates by rubbing on the shaft. The piston rods and valve stems are lubricated by oil swabs while the engine is running, the oil thus carried into the cylinder usually being all that is required for internal lubrication with saturated steam. With superheated steam, oil must be forced into the cylinder by a lubricator. The oil is distributed around the bearings by grooves cut in the white metal so arranged that oil will not leak out the ends of the bearings. The grooves are about 1/4 to 1/2 in. wide and 1/8 to 1/4 in. deep.

Water Service. Connections for circulating sea water are led to the parts of the main engine, thrust, line-shaft, and stern-tube bearings which are liable to heat. These connections may circulate water in cored passages in the part to be cooled, thereby providing indirect cooling, or the water may be allowed to flow on the part to be cooled thus providing direct cooling. The main bearings and crosshead guides are generally fitted with indirect service. Direct service through 1/2- to 3/4-in. pipes, taken off a main supply pipe, is supplied for almost every bearing, in addition to hose connections for emergency use in case of excessive local heating. These pipes are on adjustable fittings to direct the flow of water within certain limits and are fitted with valves so that they may be operated individually. The crankpins are often served by a transverse perforated pipe on each side distributing water thereby from above during a complete revolution. The thrust shoes are cored for indirect water circulation, and sometimes cooling coils are fitted in the oil chamber in the base. Direct water service is also provided by branch pipes similar to those on the main engine and so arranged that water

and stroke of main engine R = ratio of gearing C = constant. All dimensions are in inches. If a double-cylinder turning engine is used, d^2 is the sum of the squares of the two cylinders; if there are two low-pressure cylinders, D^2 is the sum of the squares of the two. For single-cylinder turning engines a safe value of the constant C is 1.75 for three-cylinder main engines and 2 for four-cylinder main engines. The constants may be reduced somewhat for

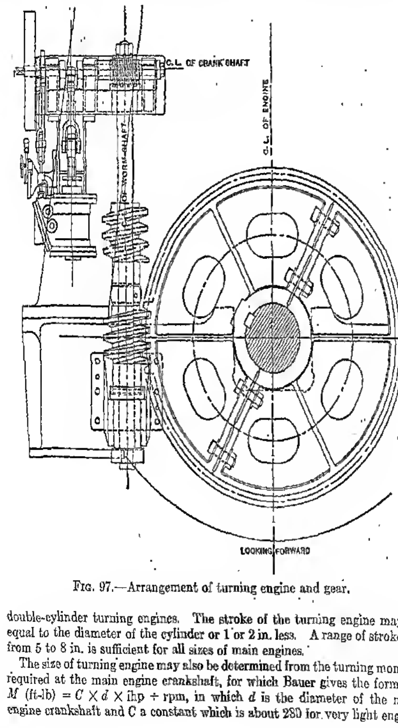

FIG. 97.—Arrangement of turning engine and gear.

double-cylinder turning engines. The stroke of the turning engine may be equal to the diameter of the cylinder or 1 or 2 in. less. A range of strokes of from 5 to 8 in. is sufficient for all sizes of main engines.

The size of turning engine may also be determined from the turning moment required at the main engine crankshaft, for which Bauer gives the formula: M (ft-lb) $= C \times d \times$ ihp $\div$ rpm, in which d is the diameter of the main engine crankshaft and C a constant which is about 280 for very light engines

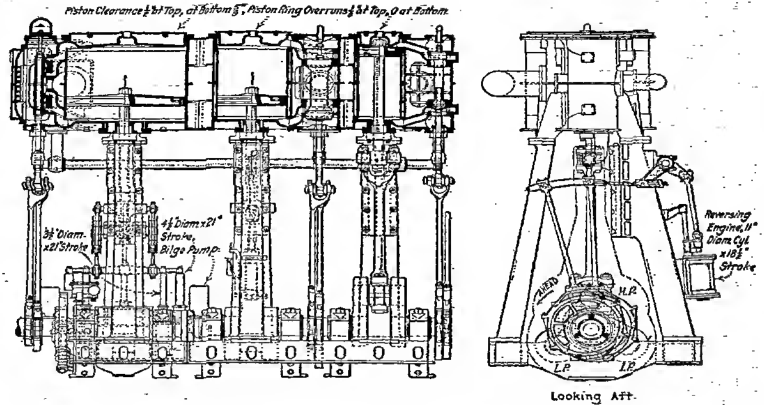

FIG. 106.—Triple-expansion engine designed and built by the Newport News Shipbuilding and Dry Dock Company.

and 560 to 670 for heavy engines. If this formula is used, the turning engine should be made large enough to give at least 1.5 times the twisting moment required, with 30 to 50 lb mep, taking into account the gear ratio and the efficiency of the gearing which will be from 13 to 15 per cent.

For merchant engines the main and auxiliary worm wheels have cast teeth and are generally of cast iron. The main and auxiliary worms are single thread and generally of cast iron although sometimes forged steel or hard bronze is used. For very large engines the auxiliary wheel may be bronze with cut teeth. The main wheel is usually split which requires that an even number of teeth be used. The pitch is made in even quarter or half inches. The following proportions of the worms and wheels may be used:

Per cent of total gear ratio in main and auxiliary gears: 75 and 25.

Pitch diam of main wheel: 4 $\times$ diam main engine crankshaft.

Pitch of teeth in main wheel: 2 in. for a 40-in. to $3\frac{1}{2}$ in. for an 80-in. wheel.

Pitch of teeth in auxiliary wheel: $1\frac{1}{2}$ to $2\frac{1}{4}$ in. for all sizes.

Pitch diam of worms: 3 $\times$ pitch.

Length of worms over teeth: 3.5 to 4.5 $\times$ pitch.

Height of teeth in wheels: 0.7 $\times$ pitch.

Height of teeth above pitch circle: 0.3 $\times$ pitch.

Thickness of teeth at pitch circle: 0.46 $\times$ pitch.

Width of face of wheels: 2 to 2.5 $\times$ pitch.

The strength of the wheel teeth, shafts, and other parts should be figured by the usual methods. The loads on the teeth may be found from the power of the turning engine, assuming a mep of 30 to 50 lb, and taking the efficiency of each worm 40 per cent, each set of thrust collars 95 per cent, and each set of bearings 95 per cent. If n_1 and n_2 = no. of teeth in the auxiliary and main worm wheels, r_1 and r_2 = radius of the auxiliary and main worm wheels, and C = 2.0 for single- and 1.5 for double-cylinder turning engines: maximum twisting moment on turning-engine crankshaft, $T = \dfrac{63{,}000 \times \text{ihp} \times C}{\text{rpm}}$.

Twisting moment on auxiliary shaft, $T_1 = T \times n_1 \times 0.40 \times 0.95 \times 0.95 = 0.36T \times n_1$.

Force on auxiliary worm wheel teeth, $F_1 = T_1 \div r_1$.

Twisting moment on main engine shaft, $T_2 = T_1 \times n_2 \times 0.40 \times 0.95 \times 0.95 = 0.36T_1 \times n_2$.

Force on main worm wheel teeth, $F_2 = T_2 \div r_2$.

Attached Pumps

On merchant ships, with engines of about 5,000 ihp and under, it is customary to drive the main air and bilge pumps through links and beams from one of the main engine crossheads, usually the low-pressure. Frequently the feed and sanitary pumps are also driven in this manner. The pumps are vertical, single-acting, and the stroke is about 45 per cent of the stroke of the main engine. The arrangement of attached pumps and gear is shown in Fig. 107.

Main Air Pumps. The bucket type of (attached) air pump in which there are foot, bucket, and head valves is shown in Fig. 98. The bucket, which is fitted with soft packing, has a depth of face of $\frac{1}{4}$ to $\frac{1}{5}$ of the diam. The pump is located so that the condensate flows from the condenser by gravity into the bottom of the pump. The down stroke of the bucket closes the foot valves and forces the trapped air and water through the bucket

may be played on each collar. The bases of the line-shaft bearings are usually piped for water circulation, while the cap may be fitted with direct service from above. The supply of water is taken from the discharge side of the main circulating or other pump, and in the case of indirect service, which is usually in use when the main engine is running, this water is returned either to some pump suction or to the bilge. The circulation for the guides is often taken from the sanitary pump in which case the water is returned to the

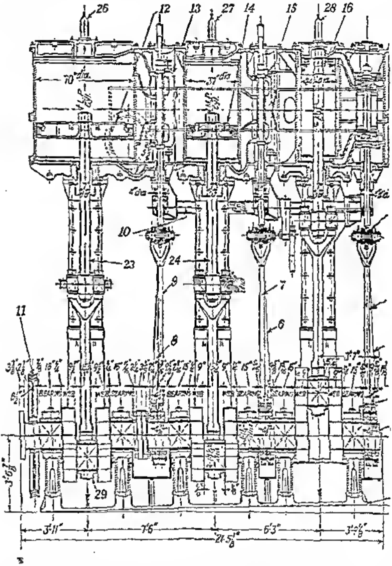

FIG. 106a.—Triple-expansion slide-valve engine used

sanitary system. The water used in direct service drains to the bilge. The water-service system for the main engine is sometimes kept separate from the system supplying the thrust bearing and line-shaft bearings on large installations, but usually one system suffices.

valves. On the up stroke the bucket valves are closed and the air and water pass through the head valves into the pump discharge. The up stroke forms a partial vacuum below the bucket which causes air and water to flow through the foot valves. The **Edwards type of (attached)** air pump in which there are only head valves (Fig. 99) is now generally used. The absence of foot and bucket valves reduces the liability to breakdown and increases the efficiency. The face of the bucket is packed by water grooves as shown and is about one-fourth of the diameter in depth. The condensate flows by gravity into the conical base of the pump and the bucket, which is also conical, on its down stroke *forces* the water through the ports to the upper side of the bucket. On the up stroke the bucket closes the ports and the trapped air and water are forced through the head valves into the pump discharge. The clearances at top and bottom of the stroke are made much smaller than for the bucket type, ¼ to ¾ in. at the top and ¾ in. at the bottom being sufficient. The angle of the bottom and the bucket is about 130 deg and that of the direction of discharge through the ports about 35 deg from the horizontal. The ports occupy about 75 per cent of the circumference of the liner and their area is 35 to 50 per cent of the area of the bucket. In this type of pump a relief valve, one-sixth to one-eighth the diameter of the pump, is always fitted at the bottom (Fig. 99) to avoid damage in starting up if an excessive amount of water has accumulated. With surface condensers the **rate of displacement of the low-pressure piston** on a double stroke **to the displacement of the air pump bucket** on a single stroke is about 28 for the bucket type and about 35 for the Edwards type. For either type the **ratio of the area through the** valves to the area of the bucket is about 0.27 and the **ratio of the area of the suction and discharge openings to the area of the bucket** is about 0.18. The air pump barrel is usually of cast iron fitted with a removable brass liner. In large sizes a manhole, which forms part of the cylinder wall, is fitted for access to the

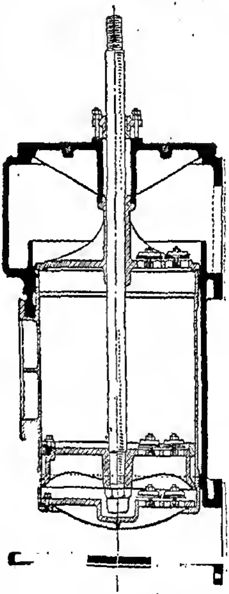

FIG. 98.—Bucket type of attached air-pump.

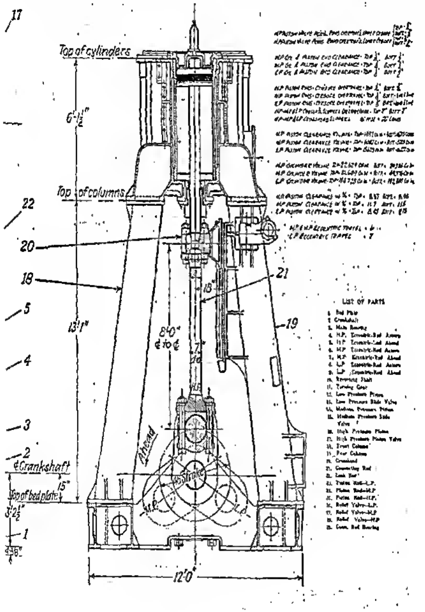
Gages and Gage Board. The engine-room gage board is usually located on the forward engine-room bulkhead near the engine control gear and within easy sight of the engineer handling the throttle. A clock and the following gages are fitted on the gage board: main steam or boiler steam; high-pressure chest; intermediate-pressure receiver; low-pressure receiver; vacuum.

Tools and Wrenches. The engine-room tool equipment should include a full set of mechanics' handtools such as vise, wrenches, hammers, chisels,



in Liberty ships. (*Courtesy of Nautical Gazette.*)

files, taps, dies, screwjack, chain falls, soldering copper, and ratchet drill. Also a full set of special wrenches for the main engine and large wrenches for the stern-tube nut and propeller nut.

Lifting Gear. Suitable lifting gear should be provided over the engine for lifting the cylinder covers and drawing the pistons and valves. This gear

valves as shown in Fig. 98. The bucket in small sizes is of brass and in large sizes of cast iron with a brass casing. The pump rod is either steel with a brass sleeve or solid tobin bronze. An extension attached to the upper end of the piston rod works in a guide as shown in Fig. 107. The thickness of the cast-iron barrel, bottom, and cover varies from about 7/8 in. for a 20-in. to 1 in. for a 30-in. pump and the brass liner from about 1/2 to 3/4 in. The valve decks are made about 1.2 times the thickness of the liner.

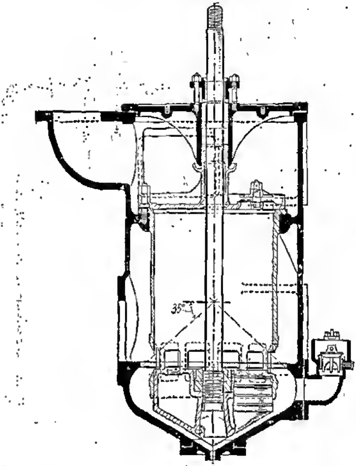


Fig. 99.—Edwards type of attached air pump.

Unless the pump discharge is taken off in such a manner that there is a head of water on the discharge valves, these valves are kept submerged by casting a rim around the valve deck or the pump cylinder as shown in Figs. 98 and 99. This head of water keeps the valves closed on the down stroke. A standpipe, open at the top, connected to and usually the same size as the discharge pipe, extends about 15 ft above the pump discharge and serves as a relief in case an abnormal amount of water enters the pump when starting up or from any other cause.

Air-pump valves are now usually made of three sheet bronze disks about 3/64 in. thick (Fig. 100). Rubber is liable to be affected by the oil which finds its way into the steam from the lubrication of the stuffing boxes. Light-

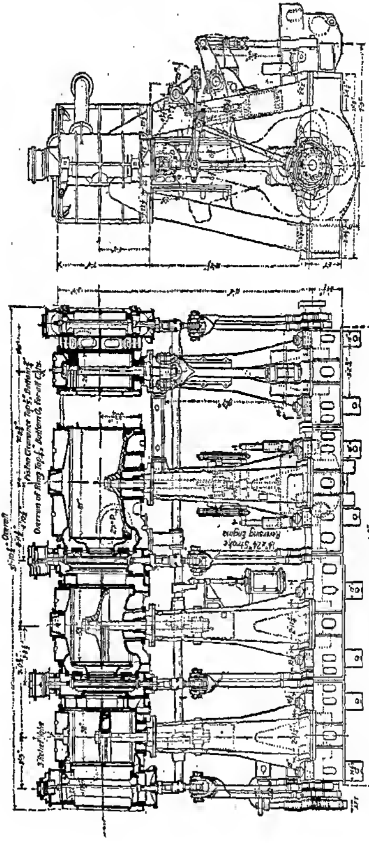

FIG. 107.—Quadruple-expansion engine designed and built by the Newport News Shipbuilding and Dry Dock Company.

ness, which is essential to good efficiency, is obtained by using brass disks. Holes in the middle and lower disks, as shown, allow the suction to act on all the disks, which assists in seating the valve and prevents the edges from curling. The valve seats, which are also brass, are in the form of grids to reduce the unsupported area of the disks. A brass guard on a stud regulates the lift of the valve which must be such that the circumferential discharge area is equal to the clear area through the seat. There may be one row of large or two rows of small valves.

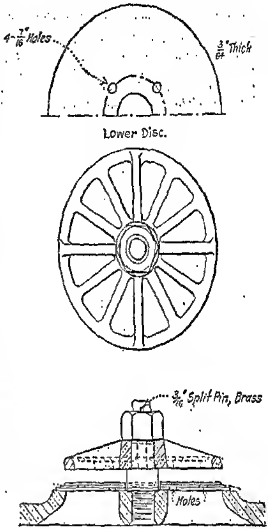

FIG. 100.—Bronze air-pump valve.

Feed pumps are of the plunger type, single-acting, and are worked from one or both ends of the air pump crosshead. The plunger works through a stuffing box fitted with metallic or soft packing. The inlet and outlet valves are carried in a valve box which is cast separate from the pump barrel to reduce the cost of replacement in case one or the other is damaged. The valves are of brass with springs to assist in seating. An air vessel and a relief valve are fitted on the pump or in the discharge piping. Feed pumps are designed for a theoretical capacity of about 2.25 times the boiler evaporation except for small engines where the ratio is increased. The evaporation may be assumed as 20 lb per ihp for compound engines, 16 to 17 lb for triple, and 15 lb for quadruple engines. Feed and other attached pumps usually have cast-iron barrels and valve boxes and brass plungers, but steel plungers are often used for feed pumps to avoid excessive wear. No definite ratios can be given for the sizes of bilge and sanitary pumps, as their capacities depend upon the type of vessel.

Attached Pump Gear. The beams are made up of two pairs of steel plates connected by a rocker shaft which works in bearings on the engine housings (Fig. 101). The link pins at each end are carried between the plates. Each link consists of two steel bars with bushings at the ends. The working parts are designed for the load on the pumps which is taken as 30 psi on the air-pump bucket and 20 psi on the plungers of the other pumps. These pressures are high enough to cover the weight of the reciprocating parts as

consists of one or more chain blocks of suitable capacity hung from travelers fitted to a strong I beam placed fore and aft above the centerline of the engine at a height sufficient to lift out the piston with rod attached. In the bottoms of the cylinders are tapped holes for eyebolts for attaching chain falls for handling the main bearing caps and other heavy parts.

Arrangement of Cylinders and Cranks. The order in which the cylinders are arranged beginning with the forward cylinder is called the order of cylinders. Different orders of cylinders is discussed under Balancing, p. 1169. The order in which the cranks pass the top center when the engine is going ahead is called the sequence of cranks. The high-pressure is commonly called the leading crank when the sequence is high-pressure, intermediate-pressure, low-pressure. Similarly the low-pressure is the leading crank when the sequence is low-pressure, intermediate-pressure, high-pressure. A right-hand engine has the working platform on the starboard side, and the cranks in passing their top position turn to the starboard. In other words, a right-hand engine turns clockwise when viewed from the after end.

Engine Designs. Figure 106 shows a triple-expansion engine in which the ports are short but not as short as if the valve chests were extended above and below the cylinders. The crankshaft is in three interchangeable and reversible sections, so that one section of spare shaft may be used for any cylinder with either end forward. The top and bottom of the eccentric straps are made from the same pattern to reduce the number of spare parts carried. Figure 107 shows a quadruple-expansion engine with the parts as short as it is possible to make them. The crankshaft is in four interchangeable but not reversible sections. The position of the links and reversing arms indicates that the engine shown in Fig. 106 has open eccentric rods and the engine in Fig. 107, crossed rods. These are representative merchant engines, the proportions and details of which are in accordance with the methods given in this section. Figure 106a shows the slide-valve reciprocating engine used in the Liberty ships during the Second World War. Figure 107a shows a uniflow engine used in the same service.

DRAFTING-ROOM METHOD OF LAYING DOWN THE ENGINE

The following method used in the design of a quadruple-expansion engine is presented by Mr. B. Meurk formerly of the Engineering Department of the Newport News Shipbuilding and Dry Dock Company:

In the engine taken as an example the crankshaft is in four interchangeable sections; piston valves are used in the high-pressure and 1st intermediate-pressure and slide valves in the 2d intermediate-pressure and low-pressure cylinders; liners are fitted in the high-pressure, 1st intermediate-pressure, and 2d intermediate-pressure cylinders. The size of cylinders, crankshaft, coupling bolts, connecting rods and bolts, crosshead, and main bearings are all determined according to the methods previously described. The best balance of a quadruple-expansion engine is obtained when the order of cylinders is high-pressure, low-pressure, 2d intermediate-pressure, and 1st intermediate-pressure and when the sequence of cranks is high-pressure, 1st. intermediate-pressure, low-pressure, and 2d intermediate-pressure, and this arrangement only is discussed.

Block out the low-pressure and 2d intermediate-pressure cylinders, valve chests, and slide valves and enough of a valve diagram (Fig. 108) to determine the stroke of the eccentrics and the areas of the passages necessary in the

well as the working pressure (or vacuum). The up stroke load is used. The pump beams are proportioned for a bending stress of about 4,500 lb at the section B (Fig. 101). If P is the total load at the pump end, A, b, and t, the width and thickness of one beam plate at B, and d the diameter of the rocker shaft in the beam plate, the stress in the beam at B $= \frac{6P \times b}{4t(b^2 - d^2)}$. The pins are proportioned for working pressures in the link bushings of about 400 lb at A and 300 lb at B. The load at C is found by multiplying the load at A by the ratio x/y. The load on the rocker shaft at B is equal to the sum of the loads at A and C. The working pressure on the rocker shaft bearings is about 150 lb. The air-pump load only is used when figuring the pump rod

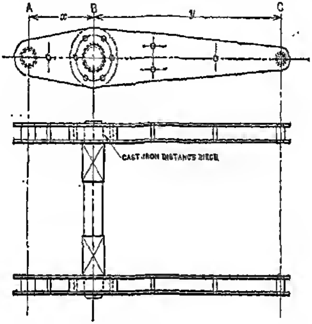

Fig. 101.—Attached pump beams.

and the bending stress in the middle of the pump crosshead. If the breadth and depth of an average section in the middle of the pump crosshead are b and h, the average diameter of the hole d, the distance between the centers of the link bearings l and the load on the pump rod P_1, the stress in the central block $= \frac{P_1 l}{4h^2(b - d)}$. The air-pump rod is figured as a column fixed at the ends, by the usual method, using a factor of safety of about 20, and also for tensile strength at the bottom of the threads, the allowable stress being about 3,500 lb. The link rods and caps are proportioned by the usual methods.

Piping and Fittings

Throttle Valves. The ability to maneuver quickly requires that the throttle valve be balanced for easy handling and arranged for convenient operation from the working platform either by a lever or a handwheel. The

cylinders and slide valves to give the proper steam and exhaust velocities. This is done to determine the shortest distance between center lines of

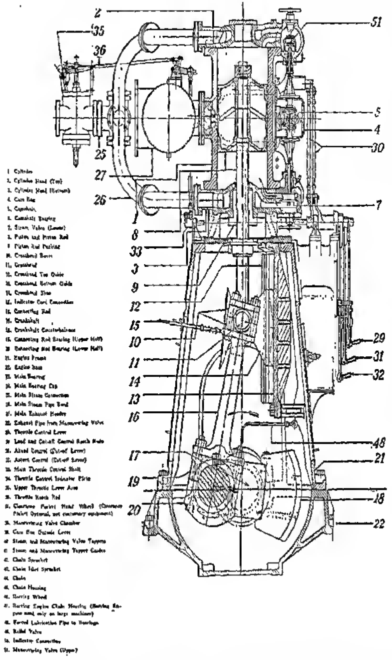

Fig. 107a.—Three-cylinder uniflow engine used

cylinders and valve stems. Lay down the crankshaft and main bearings (Fig. 108) allowing ⅛-in. clearance between the sides of the crank webs and the crankpin and main bearing brasses. The distance between main

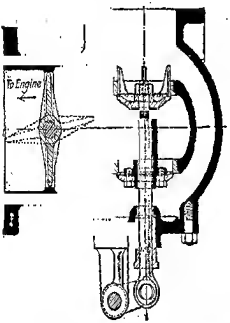

FIG. 102.—Double-beat poppet throttle valve and butterfly valve.

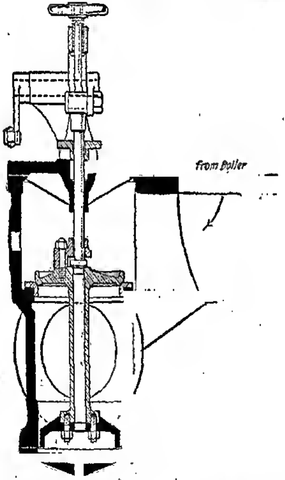

FIG. 103.—Throttle valve with balance piston and pilot valve.

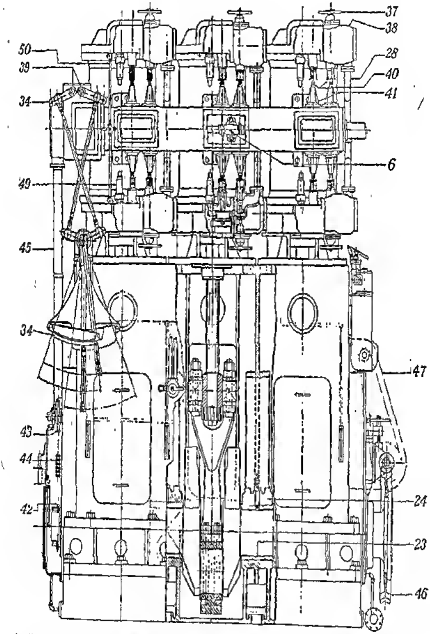
bearings Nos. (2) and (3) and Nos. (6) and (7) should be made as small as possible, clearance only being allowed for the coupling bolt nuts. The distance a is settled by allowing ¼-in. clearance between the after main-bearing brasses and the 1st intermediate-pressure eccentrics and sufficient space for the coupling bolt nuts. The outline of the cylinder and valve chest covers should next be completed (Fig. 108) facing off the covers and offsetting



in Liberty ships. (*Courtesy of Nautical Gazette.*)

the ahead eccentric rod about ½ in. if necessary to close up the centers. The width of the main bearing girders is determined by allowing the brasses to overhang about 1¾ in. at the sides to allow for fitting water-service pipes.

double-seated valve, sometimes called the double-beat poppet, shown in Fig. 102, is the type most commonly used. One disk is made slightly larger than the other so that the unbalanced pressure will act to close the valve yet not be so great as to cause difficulty in opening it by hand. To reduce the uneven expansion between the valve disks and the valve body, the distance piece between the disks is generally made of the same material as the body. If the valve is operated by a hand lever, it is well to fit a gag screw with a handwheel to limit the stroke or to lock the valve tight when in port. **Large single-seated valves should be avoided** as they are slow in closing and require special balancing arrangements which are delicate and liable to give trouble. A throttle valve **fitted with balance piston and pilot valve** is shown in Fig. 103. Unless this valve is carefully designed, it will not be balanced sufficiently to operate with a hand lever. The balance piston should be on the engine side of the valve where it is less apt to chatter than if on the steam side. The **combined disk and cylindrical valve**, fitted with a pilot valve as shown in Fig. 104 (from Bauer), is easy to balance and gives good adjustment but is rather slow to open and shut. Steam leaking through the valve liner presses the disk firmly on its seat. As the spindle rises, the pilot valve is opened, the steam above the disk escapes, and the main valve is easily operated. The flow of steam is regulated by the uncovering of the openings in the valve liner.

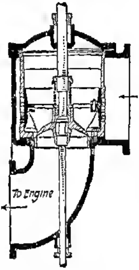


FIG. 104.

A butterfly valve (Fig. 102) is often fitted in the steam line in addition to the throttle valve for quick handling when the engine is racing. The angle of travel of the valve is generally from 60 to 90 deg. The valve is controlled by a hand lever from the working platform and is attached to the governor gear if fitted.

Governors. To prevent racing in bad weather or if the engine is suddenly relieved of its load, a governor is often fitted. **The governor may be actuated** by the pressure under the stern of the vessel or by the revolutions of the engine above a predetermined speed. In the first type a pipe is led from a chamber connected to the water at the stern to a pressure chamber at the engine fitted with a diaphragm. Any change in draft at the stern due to pitching of the vessel will vary the pressure on the diaphragm which, through suitable gear, operates the reversing engine which in turn controls the speed of the engine by moving the links. Governors of the second type may make use of the centrifugal force of revolving weights or of the force of inertia. Governors operating on the latter principle are more frequently used, one of the most popular being the **Aspinall** shown in Fig. 105. This device is carried on the air-pump beam or on a rocker arm supported on one of the housings and actuated by a link attached to the crosshead. The mechanism consists of a spring-retarded weight, *W*, whose inertia at speeds of about 5 per cent in excess of a predetermined speed is sufficient to overcome the spring and set the pawls, *PP*, so that the lower pawl on, the next up stroke, picks up the lever, *H*, which closes the throttle valve. When the speed of the engine

Before advancing further, it is well to look into different arrangements of valves and crankshaft. With the same order of cylinders, the variation in the dimensions X, Y, and Z for different arrangements of valves and crankshaft may be noted in the following table, which is made up for an engine with cylinders 26-, 38-, 55-, 81-, by 51-in. stroke.

	X	Y	Z	
Fig. 108	31 ft 10¼ in	29 ft 0¾ in	19¼ in	Crankshaft in four interchangeable sections

Fig. 110	28 ft 11¾ in	27 ft 2¼ in	8 in	Crankshaft in two interchangeable sections

After deciding on a suitable arrangement the end view is worked out (Fig. 111). Draw the crank circle and the connecting rod on the top center. Sweep the connecting rod on the crank circle a full stroke and spot the clear-

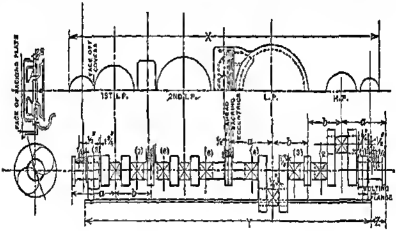

Fig. 108.

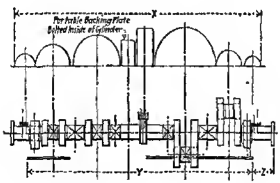

Fig. 109.

A scale of sines, tangents, and logarithms is often printed on the back of the slide. For further details concerning the use of the slide rule in various problems, see the instruction books furnished with each instrument: Wm. Cox, "Manual of the Mannheim Slide Rule"; F. A. Halsey, "Manual of the Slide Rule"; etc.

Other Types of Slide Rules. The **duplex** slide rule ($5 to $18 according to length) shows on one face the regular A, B, C, D scales, and on the other face the scales A, B', C', D (where B' and C' are the same as B and C, only numbered in the reverse order), with a runner encircling the whole scale. This arrangement makes possible the solution of more complicated problems with fewer settings of the slide, but if the rule is to be used only for simple problems, the multiplicity of scales is rather confusing. Less complicated is the **polyphase rule**, which is like a Mannheim rule with the addition of a single inverted scale, C', printed in the middle of the slide. The **log log duplex slide rule** (10 in., $8) is especially adapted for handling complex problems involving fractional powers or roots, hyperbolic logarithms, etc. A number of **circular slide rules** are on the market, the best of which are operated by a milled thumbnut, like the stem wind of a watch. The advantage of the circular rule, aside from its compact size (some models are scarcely larger than a watch), lies in the fact that the scale is endless, so that the slide never has to be reset in order to bring the result within the scale. A disadvantage is found in the necessity of reading the figures in oblique positions, or else continually turning the instrument as a whole in the hand. The **Fuller and Thacher rules** already mentioned are invaluable for problems requiring greater accuracy than can be obtained with the ordinary rules. There are also many **special slide rules**, adapted to various special types of computation, such as calculating discharge of water through pipes, horse power of engines, dimensions of lumber, stadia measurements, and electric circuits. For a description of a large variety of slide rules and other calculating apparatus, see the Catalogue of the Collection in the Science Museum, South Kensington, or Horsburgh, "Napier Tercentenary Celebration" (Royal Society of Edinburgh).

COMPUTING MACHINES

For certain purposes, computing machines have ceased to be luxuries and have become almost necessities; but they are expensive, and should be selected with reference to the special work that is to be done. The machines may be classified roughly into three groups, as follows:

Adding Machines, Non-listing. Of the machines of this kind, the most convenient in the hands of a careful operator is the well-known **Comptometer** (Felt & Tarrant Co., Chicago, Ill.; $300 to $400 according to size), or the **Burroughs non-listing** adding machine (Detroit, Mich., $175). To add a number, simply press a key in the proper column; the result appears on the dials in front of the keyboard. Multiplication as well as addition can be performed on this machine with great rapidity, and division also after a little practice. Weight, about 15 lb.

Adding and Listing Machines. The machines of this group not only add, but also print the items, totals, and subtotals. The **Burroughs** (Detroit, Mich.), the **Barrett**, and the **Wales** resemble each other in having an 81-key keyboard; the **Dalton** (Cincinnati, Ohio) and the **Sundstrand** (Rockford, Ill.) have a 10-key keyboard, admitting of operation by the touch method. On all these machines, in order to add a number, first depress the proper keys and then pull a handle (or, in the case of electrically driven machines, press a button) to record the item. The prices range from $125 to $1,100, according to size and style, new models being constantly devised for special commercial purposes.

Calculating Machines. Machines of this third group are intended primarily for multiplication and division; the types which have a keyboard can be used effectively for addition and subtraction also. They are all non-listing. The best known are the **Monroe**, the **Marchant**, and the **Millionaire**, all of which are available in either hand-driven or electrically driven models.

For graphical methods of computation, see pp. 106, 119, 170, 173–186.

Automatic calculating machines, such as those manufactured by the International Business Machines Corp., have found wide application in accounting. They are capable of a variety of simple algebraic operations; data is fed to the machines by means of perforated cards. For details see the manufacturer's bulletins, and for application to statistical methods see Baehne, "Practical Applications of the Punched Card Method" (Columbia University Press).

FINANCIAL ARITHMETIC

For the facts that are commonly required in regard to compound interest, sinking funds, etc., see the headings of the tables on pp. 64–68. More extended tables may be found in J. W. Glover's "Tables of Applied Mathematics" (Ann Arbor, Mich., 1923).

ance line, being sure that the line covers all projecting parts such as setscrews. This line should clear the bedplate and housings by about 2½ or 3 in. Next work out the conditions surrounding the upper end of the connecting rod including the crosshead, piston-rod stuffing boxes, pistons, and bottom and

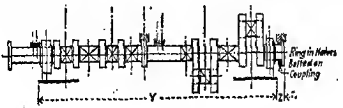

FIG. 110.

top of high-pressure and low-pressure cylinders. Sufficient space should be allowed for the piston-rod packing and gland to accommodate any type of metallic packing commonly used, as the type of packing is often changed.

The length of the eccentric rod is determined by laying down the valve in its bottom position and locating the bottom valve chest cover with its stuffing box and gland. The clearance between the gland and the guide face on the valve stem should be sufficient to allow repacking the gland with the valve in its top position. The length of the guide face should be such as to allow the valve stem facing to overrun at top and bottom in maximum linked-up gear. The valve-stem guide and the main links in their top position may then be located, allowing ample space between the links and the guide bracket for oil cups on the link block and eccentric rod. The length of eccentric rod is then the distance between the center of the links and the top of the eccentric circle drawn on the crank center.

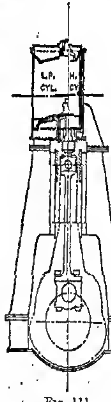

FIG. 111.

To locate the reverse shaft center, lengths and reversing-engine arm and reversing arms, angle of slot in reversing arms, and outer end of the suspension rod, it is necessary to plot the paths of the eccentric-rod pins on the links for full gear ahead and astern and maximum linked-up astern positions. The motion of the main links is determined by the suspension rod and the two eccentric rods. The point where the suspension rod attaches to the link moves in a circular arc with a radius equal to the length of the rod. The point where the astern eccentric rod is attached to the link has a compound motion due to the ahead eccentric rod and the suspension rod which causes the point to travel through a figure eight. This figure should be plotted for the link positions mentioned above and the reverse shaft, reversing arms, and outer end of suspension rod located to give the smallest possible slotting action of the link block. It is also advisable to check the clearances between the link block and the connecting pins at the ends of the links for the corresponding link positions. Figure 68 shows the

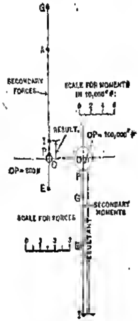

Fig. 118.—Secondary-force and moment polygons.

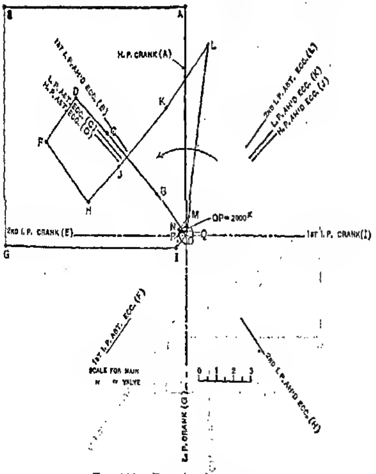

Fig. 119.—Rotating-force polygon.

slotting action of the link block for full gear ahead, linked-up ahead, full gear astern, and linked-up astern positions.

BALANCING

The following text was prepared by Mr. J. B. Woodward, Jr., of the Engineering Department of the Newport News Shipbuilding and Dry Dock Company:

The object in balancing marine engines is to avoid vibrations in the ship's structure. The tremors produced by pounding in the engine due to slack bearings or improper valve setting are also objectionable but should not be confused with the vibrations caused by the unbalanced forces. The magnitude of the unbalanced forces is dependent upon the weight and size of the moving parts and the speed of rotating of the engine, but is independent of the steam pressure. When the piston with its attached weights is being accelerated, that portion of the steam pressure necessary to accelerate it is absorbed in giving energy to the moving parts and is not transmitted to the engine framing. It follows that the pressure on the cylinder head is only partly balanced by that portion of the steam pressure upon the piston which is transmitted to the engine framing by way of the piston rod, connecting rod, and crankshaft. It is obvious then that the unbalanced forces developed when an engine is revolving are equal and opposite to the forces necessary to accelerate or retard the moving parts.

Analytical Method

The most serious unbalanced forces are those which act in a vertical direction. The horizontal forces in a vertical engine are much smaller, also the ship itself is usually stiffer in the horizontal plane. In determining forces, the moving parts are divided into two groups, reciprocating and rotating, and the cylinder and valve gear parts are treated separately, as follows:

1. Cylinder Reciprocating Parts. Pistons, piston rods, crossheads, and top half of connecting rods. The connecting rod is divided into two parts at the center of gravity, one assumed to move with the crosshead and the other to revolve with the crankpin. The location of the center of gravity of the connecting rod may be assumed with sufficient accuracy.

2. Valve Gear Reciprocating Parts. Valves, valve stems, balance pistons, links and blocks, ahead eccentric rods, one-half the astern eccentric rods, and one-half the suspension rods.

3. Cylinder Rotating Parts. Crank webs, crankpins, and bottom half of connecting rods.

4. Valve-gear Rotating Parts. Ahead and astern eccentrics and straps.

Formulas for Vertical Forces. The rotating parts of an engine give rise to a force which is constant in amount but variable in direction while the reciprocating parts set up a force constant in direction but variable in amount. In dealing with the rotating parts, only the vertical component of the force will be considered.

Assume A = length of crank arm, B = length of connecting rod, $U = B \div A$, b = length of eccentric rod, a = throw of eccentric, $u = b \div a$, l = sum of the mean of top and bottom steam laps and the mean of top and bottom steam leads, N = revolutions per sec, and θ = angle of the crank from

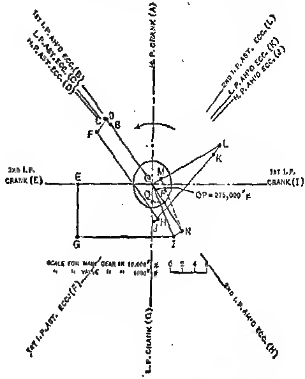

Fig. 120.—Primary-moment polygon.

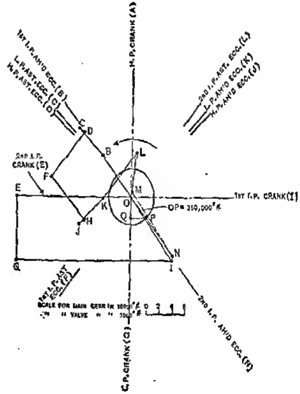

Fig. 121.—Rotating-moment polygon.

the vertical axis. All dimensions are in feet. Then for a single-cylinder engine, or for each cylinder of a multi-cylinder engine:

$$\text{Cylinder reciprocating parts: } F_1 = \frac{4\pi^2}{32.2} N^2 A W_1 \left(\cos\theta + \frac{1}{U}\cos 2\theta\right)$$

$$= 1.226 N^2 A W_1 \left(\cos\theta + \frac{1}{U}\cos 2\theta\right) \quad (1)$$

where W_1 = the weight of the parts

$$\text{Valve-gear reciprocating parts: } F_2 = 1.226 N^2 a W_2 \cos\theta \quad (2)$$

where W_2 = weight of the parts

The second term $\frac{1}{U}\cos 2\theta$ has been neglected, as the weight of the valve gear is small compared with the cylinder parts and as the ratio of eccentric rod length to eccentricity is relatively large.

$$\text{Cylinder rotating parts: } F_3 = 1.226 N^2 A W_3 \cos\theta \quad (3)$$

where W_3 = weight of the parts

$$\text{Valve-gear rotating parts: } F_4 = 1.226 N^2 l W_4 \cos\theta \quad (4)$$

where W_4 = weight of the parts

Application of Formulas. To show the application of the formulas the vertical forces will be computed for a triple-expansion engine of the usual marine type with cranks at 120 deg.

Example. Engine size is 20½-35-60 in. × 42-in. stroke with attached air and bilge pumps driven by a beam from the low-pressure crosshead. The order of cylinders from the forward end is high-pressure, intermediate-pressure, and low-pressure. Designed ihp is 1,500 at 85 rpm. As the crank webs, crankpins, and connecting rods are the same for the three cylinders, there is no unbalanced force arising from the cylinder rotating.

Table 17

Designed rps (N) (85 ÷ 60)	1.42
Length of crank arm (A), ft	1.75
Length of connecting rod (B), ft	7.50
Connecting rod ratio (U)	4.28
1.226 N^2A	4.31

Size and type valve	H-p 8-in. piston	I-p 14-in. piston	L-p double-ported slide
Valve takes steam	Inside	Inside	Outside
Throw of eccentric (a)—ft	0.33	0.33	0.27
Angle of advance	36°-38′	28°-22′	42°-30′
Sum of mean steam lap and mean steam lead (l)—ft	0.20	0.21	0.18
Weight in lb			
Piston	560	1,400	2,850
Valve-gear reciprocating parts	930	1,200	2,560
Valve-gear rotating parts	2,100	2,100	1,200

on a crank angle base (Fig. 122). The projection OQ of OP on the vertical axis represents the magnitude of the vertical force due to the reciprocating parts when the high-pressure crank is passing the top center. By revolving OP about O and finding its projection on the vertical axis for any position, the vertical force of the reciprocating parts may be found for the corresponding high-pressure crank angle. Thus, if it is desired to find the force when the high-pressure crank has moved 20 deg from the vertical position, it is only necessary to revolve OP 20 deg in the direction of rotation and obtain its projection on the vertical axis.

The secondary-force polygon (Fig. 118) is constructed in a manner similar to the primary polygon except that each weight is laid off in a position corresponding to double the angle in Fig. 115. As a rule, the virtual secondary weights of the valve gear may be neglected as is done in this case. The closing line (IO) of the polygon is multiplied by $1.226N^2A \div (B/A) = 0.79$ and laid off (OP) to the scale of forces in Fig. 122. In finding the vertical forces OP is revolved at twice the rate of the high-pressure crank and projected on the vertical axis.

The rotating-force polygon (Fig. 119) is drawn in a manner similar to the primary polygon for the reciprocating parts, and the same factor 3.54 is applied to the closing line. The horizontal forces, if desired, may readily be obtained by projecting OP on the horizontal axis.

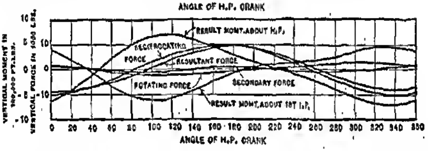

FIG. 122.—Unbalanced vertical forces and rocking moments—quadruple-expansion engine.

Moment polygons (Figs. 118, 120 and 121) are plotted in the same manner as the force polygons, using moments instead of weights and applying the same factors to the closing lines as in the force polygons.

Force and Moment Curves (Fig. 122). The reciprocating and rotating forces are plotted on a crank angle base and combined into a single resultant vertical force. The moments about the forward crank may be plotted and combined in the same manner. The resultant moment only is shown in Fig. 122. The resultant moment about the after crank is also shown.

Means of Improving Balance

In a single-crank engine, the unbalanced force of the rotating parts can be compensated for by a **counterweight** on the crank equal in weight to the rotating parts. If the counterweight be made equal to the rotating and reciprocating parts, the unbalanced force of the latter also disappears, but a new horizontal force is introduced equal to the radial acceleration of the reciprocating parts.

In a two-crank engine, revolving balance may be secured by the use of counterweights opposite each crank and, if balance of the reciprocating parts is necessary, it is probably best to use lever balance weights for each cylinder. Perfect balance may be secured only by special arrangements in which the cranks are no longer at 90 deg.

The arrangement of cylinders generally used in **three-crank triple-expansion engines** counting from the forward end is high-pressure, intermedi-

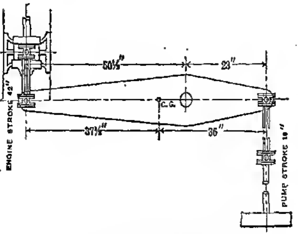

FIG. 112.—Arrangement of attached pumps.

parts. When these parts are not of the same size, the unbalanced force for each crank may be calculated by formula 3. Except for the pump lever pins on the low-pressure, crosshead (which are included with the pump gear in Table 18) the piston rods and crossheads are also alike for the three cylinders. Their resultant force for this crank arrangement is zero, and they may be omitted from the computation. The connecting rods are omitted for the same reason. The low-pressure eccentrics are on the shaft while the other eccentrics are on the shaft couplings. The data required are given in Table 17.

The attached pumps (Fig. 112) may be combined with the cylinder reciprocating parts by determining the force which would have to be applied at the low-pressure crosshead to balance the combined moment of the whole gear (Table 18). The obliquity of the links may be neglected as its effect is small.

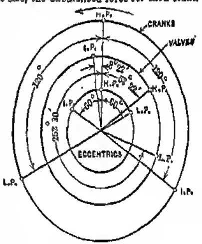

FIG. 113.—Arrangement of cranks and eccentrics—looking aft.

Table 18

Item	Weight, lb	Arm about beam axis, in.	Moment about beam axis, in.-lb
Pump plungers, bucket and rod	350	23.0	8,050
Pump crosshead	250	23.0	5,750
Pump links and link pins	230	23.0	5,290
Crosshead links and link pins	150	−50.5	−7,570
Crosshead pins	20	−50.5	−1,010
Pump beam	405	−13.0	−5,265
Resultant	1,405	+3.73	5,245

ate-pressure, and low-pressure with the cranks at 120 deg. The crankpins and webs and also the piston rods, crossheads, and connecting rods are usually made the same for all three cylinders. With such an arrangement the balance may be improved by increasing the weight of the high-pressure piston and lightening the low-pressure so as to make the weights of the reciprocating parts as nearly equal as possible. Even when the crank webs are of unequal thickness it is seldom advisable to add weight and complication to the engine by using counterweights to balance the rotating masses.

In **four-crank engines** Bauer and Robertson state that balancing is most effectually carried out when (1) the cylinders with the heaviest connecting rods are in the center and (2) the distance between the two middle cylinders is as large as possible, as compared with the distance between the two cylinders at either end of the engine. "If these conditions cannot be secured in practice, the outer connecting rods must be artificially lightened by means of counterweights and the connecting rods of the middle cylinders artificially weighted by the use of heavy pistons. In triple-expansion engines good balancing is most easily obtained by having two low-pressure cylinders, each doing purposely less work and having lighter connecting rods than the high-pressure and intermediate-pressure cylinders, outside which they are placed. An engine with four cranks, in which the forward pair of cranks is at right angles to the after pair, and the cranks of each pair are at an angle of 180 deg to each other, gives an almost perfect balance, if the distance between the two pairs of cranks is relatively large in proportion to the distance between the individual cranks constituting each pair, and when the masses of the forward pair are equal to the masses of the after pair." Four-cylinder quadruple-expansion engines should be arranged with the high-pressure and 1st intermediate-pressure cylinders on the ends and the 2d intermediate-pressure and low-pressure inside, with the attached pumps, if any, driven by a beam from the low-pressure crosshead. The low-pressure piston should be made as light as possible. The pair of cylinders on each end should be as close together as practicable, which is facilitated by placing the valves for the high-pressure and the 1st intermediate-pressure cylinders at the ends of the engine and the valves for the other two cylinders in the middle.

Revolving balance may be obtained in four-crank engines in a number of ways, simplicity and cheapness usually being the determining factors. Instead of fitting balance weights opposite each crank, two revolving counterweights are often used, one forward of the engine framing and the other aft. The turning wheel may generally be used for the attachment of one weight, and the other may be made in the form of a disk attached to the forward end of the crankshaft, extended a few inches if necessary. The amount and angular position of such weights may be readily determined from the force and moment polygons. Whether or not counterweights are used it is well to consider the advantage to be gained by drilling holes in one or more crankpins if solid, or filling one or more with lead if hollow.

Yarrow-Schlick-Tweedy System. Complete primary balance can be obtained in four-crank engines on the assumption of infinite connecting rods, thus eliminating the secondary forces from consideration. The balance is complete if (1) the sum of the moments of the horizontal forces and the sum of the moments of the vertical forces about the forward crank = 0 and (2) the sum of the moments of the horizontal forces and the sum of the moments of the vertical forces about the after crank = 0. By proper choice of crank angles and by changing weights of moving parts and cylinder spacing, in so

Table 19. Vertical Forces

H-p crank angle	Cylinder reciprocating parts						Valve gear			Total resultant
	H-p	L-p	I-p	Cylinder resultant	Attached pump	Resultant including attached pumps	2,772 × cos θ	1,578 × sin θ	Resultant

far as the design of the engine permits, it is possible to approximate very closely the above conditions.

The work is best done graphically. The vertical moment about the forward crank is found for each cylinder and valve, using for the cylinder weights the sum of the actual weights of the cylinder reciprocating and rotating parts, and for the valve-gear weights the sum of the virtual weights of the valve-gear reciprocating and rotating parts. The horizontal moment about the forward crank is found for each cylinder and valve, using the actual weights of the cylinder rotating parts and the virtual weights of the valve-gear rotating parts. The moments about the after crank are obtained in the same manner. The four moment polygons are then plotted by laying off each moment parallel to its corresponding crank or eccentric position (see Graphical Method). The sum of the moments represented by a particular polygon is zero when the polygon is a closed figure. All the polygons may usually be made very nearly or entirely to close by properly choosing the angles, weights, and cylinder spacing. If necessary, counterweights may be used at the forward and after ends of the engine, the amount and position of such weight being determined in each case from the moment polygons. If the ratio $L \div l$, in which L is the length between center lines of the pair of cylinders at either end of the engine and l the distance between center lines of the inner pair of cylinders, is less than $\frac{5}{3}$, the angles of the two outer cranks are apt to be small, which has an injurious effect upon the maneuvering qualities and the regularity of the turning moment. If the cylinders with the heaviest moving parts are placed in the middle and $L \div l$ made about 2, the best crank angles will be obtained, the smallest being about 65 to 70 deg, and complete balance can be obtained without the use of counterweights.

A full description of the Yarrow-Schlick-Tweedy system of balancing may be found in Bauer and Robertson.

Critical Revolutions and Vibrations of Hull. It is important that the rpm of the engine at its working speed do not coincide with the natural period of vibration of the ship. In cases where heavy vibrations have been set up they have been relieved by changing the working revolutions of the engine. The number of revolutions which produces the maximum vibratory effect is given by Bauer and Robertson from the formula derived by Schlick (*Trans. of the Inst. of Naval Architects*, 1894) as follows:

$$N = K\sqrt{T \div DL^3}$$

where N = rpm

T = the moment of inertia of the midship section in foot units

D = the displacement in tons

L = the water-line length, ft

K = a constant having the following values:

For large fast ships with fine lines, $K = 1.872 \times 10^5$

For cargo vessels with full lines, $K = 1.668 \times 10^6$

Investigations by Mr. William Gatewood on an oil tank steamer, *Trans. Soc. Nav. Arch. and Mar. Engrs.*, 1915, gave results closely in agreement with the above formula.

TURNING EFFORT

While it is important that the resultant of the tangential forces acting upon the crankpins, frequently called the turning effort, be as uniform as

A weight of 104 (= 5.245 ÷ 50.5) lb applied at the crosshead end would completely balance 1,405 lb with a moment of 5.245 in.-lb. The effect of the attached pumps is then virtually to reduce the low-pressure cylinder reciprocating weight by 104 lb. It is better, however, to treat this weight separately as in Table 19 rather than to combine it with cylinder weight.

The arrangement of the cranks and valve gear is shown diagrammatically in Fig. 113. The position shown for the eccentric in each case is the mean position of the ahead and astern eccentrics.

Calling the angle of the high-pressure crank θ, the formulas become:

Cylinder Reciprocating Parts:

H-p, $$F_1 = 2{,}420\left(\cos\theta + \frac{\cos 2\theta}{4.28}\right)$$

I-p, $$F_1 = 6{,}040\left[\cos(\theta - 120^\circ) + \frac{\cos 2(\theta - 120^\circ)}{4.28}\right]$$

L-p, $$F_1 = 12{,}300\left[\cos(\theta + 120^\circ) + \frac{\cos 2(\theta + 120^\circ)}{4.28}\right]$$

Attached pumps, $$F_1 = 450\left[\cos(\theta - 60^\circ) + \frac{\cos 2(\theta - 60^\circ)}{4.28}\right]$$

Valve-gear Parts:

		H-p	I-p	L-p
Angle of valve from h-p crank	=	$306^\circ - 38'$	$8^\circ - 22'$	$252^\circ - 30'$
1.226 N^2aW_2	=	702	985	1,670
1.226 N^2W_4	=	1,035	1,090	535

Then the resultant force of the valve-gear reciprocating parts, $F_2 = 762 \cos(\theta + 306^\circ\text{-}38') + 985 \cos(\theta + 8^\circ - 22') + 1{,}670 \cos(\theta + 252^\circ\text{-}30') = (762 \cos 306^\circ\text{-}38' + 985 \cos 8^\circ\text{-}22' + 1{,}670 \cos 252^\circ\text{-}30') \cos\theta - (762 \sin 306^\circ\text{-}38' + 985 \sin 8^\circ\text{-}22' + 1{,}670$

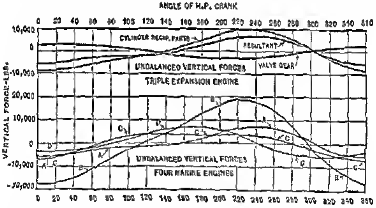

FIG. 114.—Curves of unbalanced vertical forces.

$\sin 252^\circ\text{-}30') \sin\theta = 925 \cos\theta + 2{,}060 \sin\theta$. The resultant force of the valve-gear *rotating* parts, $F_4 = 1{,}035 \cos\theta + 1{,}090 \cos(\theta + 60^\circ) + 535 \cos(\theta - 60^\circ) = 1{,}847 \cos\theta - 482 \sin\theta$.

The total force of the valve gear is then $= 2{,}772 \cos\theta + 1{,}578 \sin\theta$.

The vertical forces of the cylinder parts and the valve gear and the resultant vertical force are given in Table 19 and are shown graphically on a crank angle base in Fig. 114. *The resultant vertical forces for the four engines below* are shown in Fig. 114.

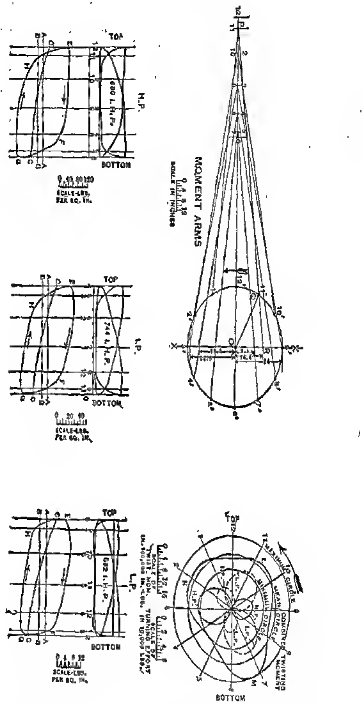

Fig. 123.—Construction of twisting-moment diagram for triple-expansion engine.

Curve	Size, in.	Rpm	Ihp	Order of cylinders	Sequence of cranks
A	20½-35-60 × 42 stroke	85	1,500	H-p, i-p, l-p	H-p, i-p, l-p
B	31-50-84 × 54 stroke	82	4,000	H-p, i-p, l-p	H-p, i-p, l-p
C	35-58-69-69 × 60 stroke	75	5,500	F-l-p, h-p, i-p, a-l-p	F-l-p, a-l-p, h-p, i-p
D	24-35-51-75 × 51 stroke	70	2,600	H-p, l-p, 2 i-p, 1 i-p	H-p, 1 i-p, l-p, 2 i-p

In all cases the cranks are equally spaced and the cylinder rotating parts are balanced in all cases except *B*, where the crank webs are of unequal thickness. In large three-cylinder triple-expansion engines (*B*), the vertical forces are necessarily great unless a counterweight is used opposite the low-pressure crank to offset the effect of the heavy piston, which however is not often done. No counterweights have been used in any of the above engines.

Rocking Moments. As the unbalanced forces of the various cylinders act at different points along the axis of the engine, unbalanced moments arise which tend to tilt, or rock, the engine in a *fore-and-aft* direction. It is convenient to refer these moments to a horizontal axis at right angles to the axis of the crankshaft and passing through the intersection of the crankshaft axis with the center line of the forward cylinder. The arms are then measured from the point of intersection to the axis of the various cylinders and valves. Where there is a valve forward of the point of intersection, its arm is considered negative. The formulas for the rocking moments may be derived from formulas (1), (2), (3), and (4) by inserting a factor in each to represent the arm about the given axis expressed in feet.

Primary and Secondary Forces and Moments. It is useful, particularly in representing the forces graphically, to separate the force due to the reciprocating members into two parts, one part varying as cos θ and called the **primary force**, and the other varying as cos 2θ and called the **secondary force.** Corresponding to the primary and secondary forces there are also primary and secondary moments. The weights for the secondary forces, as may be seen in formula (1), are only $1/U$ times the weights for the primary forces. However, it should be borne in mind that the forces or moments, thus separated for convenience into primary and secondary parts, actually appear combined as a single force or moment.

Graphical Method

The method given here is based on Rear-Admiral D. W. Taylor's paper "Balancing Marine Engines," *Trans. Soc. Nav. Arch. and Mar. Engrs.*, 9.

Polygons are drawn for the primary and for the secondary forces due to the reciprocating parts, and for the forces due to the rotating parts. The corresponding moment polygons are also drawn. In order to combine the valve gear in the same polygon with the main gear, the valve weights are reduced to virtual weights, having the travel of the piston for reciprocating weights and revolving with the crank radius for rotating weights. The reduction factor for the primary polygons is the ratio of valve travel to engine stroke ($a \div A$); and for the secondary polygons, the factor is the product of the ratio of valve travel to stroke ($a \div A$) by the ratio of the throw of the eccentric to the length of the eccentric rod ($a \div b$).

possible throughout the revolution to ensure steadiness of running and to reduce the stresses in the shafting, it is not as a rule necessary to construct the turning effort diagram, unless the design departs from usual practice, in which case it is advisable to construct a set of theoretical indicator cards and proceed as outlined below. It is sufficient for the purpose of calculating shafting stresses to know the ratio of maximum to *mean twisting moment*, which has the same value as the ratio of maximum to mean turning effort. The value of this ratio is given for various types of engines on p. 1106. **Variation in the turning effort is due to** (1) unequal distribution of power in the different cylinders, (2) variation in steam pressure on the pistons, (3) weight and inertia of the moving parts, and (4) the angularity of the connecting rod. In general **the greater the number of cranks the more uniform the turning effort.**

The turning effort on any one crank in pounds multiplied by the crank radius in inches gives the twisting moment on the shaft in pound-inches for that particular crank. The same result is more conveniently obtained if the net vertical force on the piston due to steam pressure and to inertia and dead weight of the moving parts is multiplied by OR (Fig. 123) the distance from the shaft center O to the intersection of PQ, the centerline of the connecting rod, with the axis XOX. The turning effort may be readily obtained from the twisting moment by dividing by the crank radius, or from the twisting moment diagram (Fig. 123) by applying the proper scale.

For all practical purposes the indicator cards may be assumed to be taken on the same revolution of the engine. On the crankpin circle (Fig. 123) lay off the points 1', 2', 3', 4', etc., 30 deg apart and locate the corresponding *points* 1, 2, 3, 4, etc., *in the travel of the piston.* Locate these piston positions for each set of cards, and at each position erect an ordinate. At any position of the down stroke the intersection of the ordinate between the down stroke line of the top card and down stroke line of the bottom card represents the difference in steam pressure on the top and the bottom of the piston; and in similar manner for any up stroke position. The ordinates from the base line AA to $EFGH$ show the pressure difference on the pistons in pounds per square inch for a complete revolution, ordinates above AA representing downward and ordinates below, upward pressure.

The moving parts are being accelerated during the early portion of the stroke, and their inertia must be subtracted from the steam pressure on the piston; during the later portion the parts are being retarded and their inertia must be added to the steam pressure. **The inertia force** (F) may be calculated by the formula

$$F = 1.226N^2AW\left(\cos\theta + \frac{\cos 2\theta}{U}\right),$$

where N = rps

A = length of crank arm, ft

U = ratio of connecting rod length to crank arm

θ = angle of the crank

W = weight in lb of the piston, piston rod, crosshead, and top half of connecting rod

Attached pumps should be treated as described under Balancing, p. 1160. The vertical component of the centrifugal force of the rotating parts is not considered as, when combined with the horizontal component, the resultant is a

The valve gear is here separated into (1) ahead reciprocating parts, consisting of valves, valve stems, balance pistons, link blocks, and one-half the links, suspension rods, and ahead eccentric rods; (2) astern reciprocating parts, consisting of one-half the links and astern eccentric rods; (3) ahead rotating parts, consisting of the ahead eccentrics and straps and one-half the ahead eccentric rods; and (4) astern rotating parts, consisting of astern eccentrics and straps and one-half the astern eccentric rods.

Example. The method will be applied to a quadruple-expansion engine 26-in., 38-in., 55-in., 81-in. by 51-in. stroke designed for 3,000 ihp at 70 rpm. The particulars of the engine and the data required to construct the polygons are given in Tables 20 and 21.

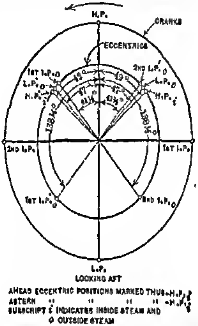

Fig. 115.—Arrangement of cranks and eccentrics.

The arrangement of cranks and eccentrics is shown in Fig. 115 and the arrangement of cylinders and valves in Fig. 116. The air, bilge, and sanitary pumps attached to the low-pressure crosshead have an upward resultant of 560 lb, which is subtracted from the low-pressure reciprocating weights.

Table 20

Designed rps (N) (70 ÷ 60):	1.167
Length of crank arm (A), ft	2.125
Length of connecting rod (B), ft	9.580
Connecting rod ratio (U)	4.500
Length of eccentric rods (b), ft	9.250
$1.226N^2A$	3.540

	H-p	1st i-p	2d i-p	L-p
Travel of valves, in	8.0	8½	8½	9.0
Primary reduction factor for valve-gear weights	0.1570	0.1670	0.1670	0.1760
Secondary reduction factor for valve-gear weights	0.0057	0.0064	0.0064	0.0071

radial force. The friction, weight, and inertia of the valve gear has little effect upon the turning effort and need not be considered.

The dead weight w, which includes all of W and in addition the bottom half of the connecting rod, the crankpin, and the eccentric portion of the webs, must be added directly to the pressure on the piston during the down stroke and subtracted during the up stroke. In Fig. 123, if BB be laid off from AA as a base to represent w per sq in. of piston area and CC laid off from BB to represent F per sq in. of piston area, then the ordinates between CC and $EFGH$ will represent the vertical pressure per square inch on the piston due to the steam and to the weight and inertia of the moving parts.

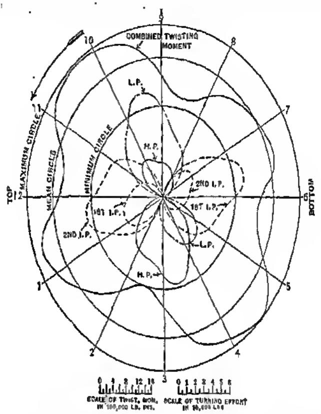

FIG. 124.—Twisting-moment diagram for quadruple-expansion engine.

In Tables 23 to 24 the data and calculations and in Fig. 123 the twisting moment diagram are shown for a 24½ in.-41½ in.-72 in. × 48 in. stroke triple-expansion engine. The length of the connecting rod is 9 ft and the rpm = 72. The twisting moment in pound-inches is plotted radially on the corresponding crank position for each crank separately, and the three smaller figures then combined into the resultant LMN. The ratio of the maximum to the mean twisting moment as shown by the figure is 1.32. The mean twisting moment is 1,800,000 lb-in. against 1,850,000 lb-in. by the formula (63,000 ihp ÷ rpm).

In Fig. 124 is shown the twisting-moment diagram for a 27-in., 39-in., 58-in., 87-in. by 54-in. stroke quadruple-expansion engine turning at 85 rpm. The ratio of maximum to mean twisting moment in this case is 1.233.

Primary-force Polygon (Fig. 117). From O as a center to a convenient scale construct the polygon $OAEGI$ of which each side represents by its length the weight (Table 21) of the cylinder reciprocating parts for one of the four cranks and parallels the crank position. The letter at the end of each line is the same as that marking the corresponding crank position. In similar manner construct the polygon $OBCDFHJKL$ for the valve-gear reciprocating parts, the sides being equal in length to the virtual primary weights (Table 21) of the various valve-gear reciprocating parts and parallel to the corresponding eccentric positions. On account of the relatively small weight of the valve gear it is convenient to use a larger scale for the valve-gear polygons. The closing line LO to the scale of the main polygon $OAEGI$ reduces to MO. IO and MO are combined by means of the parallelogram $OMNI$ into NO, which then represents the weight and position of an imaginary weight which revolving on the crank radius would completely balance the primary forces of the main and valve-gear reciprocating parts. To obtain the absolute value of the vertical force, ON is multiplied in length by $1.226N^2A$ ($= 3.54$) and the new line OP laid off to the scale which it is desired to use when plotting the forces

* Including steam pressure, inertia force, and dead weight.

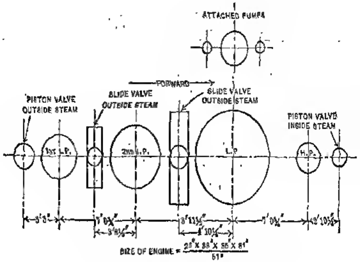

Fig. 116.—Arrangement of cylinders and valves.

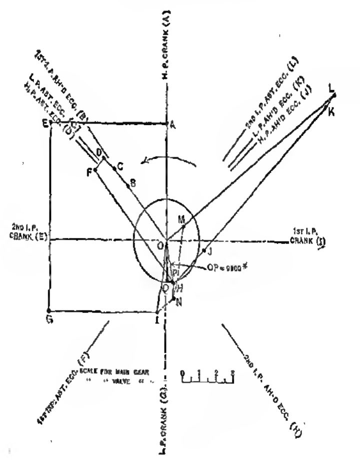

Fig. 117.—Primary-force polygon.

Revolutions for Different Percentages of Full Power. The revolutions of reciprocating engines corresponding to different indicated horsepowers may be taken from the curve in Fig. 125 which is plotted from data from a number of engines. If the revolutions for full power are known, the revolutions for other powers will agree closely with values taken from the curve.

Backing Power of Marine Engines. In reversing a reciprocating engine a much greater proportion of ahead full power can be obtained than in a turbine installation in which the backing turbine is a separate element, the power of which is kept as low as consistent with safety in handling the ship in order to reduce the turbine size. Commander S. M. Robinson in the *Jour. A.S.N.E.* for February, 1916, gives the results of the backing trials of the battleship "Delaware" when suddenly reversed from full speed ahead. At the beginning, 44 per cent of full ahead power (28,500 ihp) was developed at 40 per cent of ahead revolutions (130 rpm), which had increased to 55 per cent at 54 per cent of revolutions when the vessel stopped. The maximum power developed as the backing continued was 81 per cent at 74 per cent of revolutions. The Coast Guard cutter "Tallapoosa," when reversed, developed 53 per cent of full ahead power (1,000 ihp) at 62 per cent of ahead revolutions (129 rpm), 60 per cent at 78 per cent of revolutions and 90 per cent at 109 per cent of revolutions. The torque developed while backing often exceeds the full power ahead torque, the backing trials of the "Delaware" showing about 9 per cent excess.

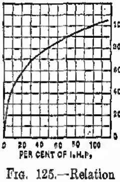

Fig. 125.—Relation of ihp and rpm.

WEIGHTS AND DIMENSIONS

Weights of Marine Engines. There are many methods, some of which are very complicated, for estimating the weights of marine engines. For most purposes, the total weight of the engine is all that is desired and that may be obtained in several ways, the most direct of which is based on ihp. The following **weights per ihp of vertical marine engines** will give a general idea of the weights of different types: compounds, 65 to 75 lb; three-cylinder triples, 85 to 110 lb; quadruples, 110 to 135 lb. However, on account of the different ratings of ihp which the same size engine may have, the total weight may be estimated much more closely if based on cylinder volumes; or, for the sake of simplicity, the sum of the squares of the cylinder diameters multiplied by the stroke, all in inches, which may be designated as Σ. The product of $\Sigma \times$ constant C (which varies with the number of cylinders and the length of stroke) closely approximates the weight of the engine. C for vertical marine engines, exclusive of attached pumps and condensers, for engines with 24 to 40 in. stroke may be taken as follows: 0.9 to 0.75 for three cylinder triples; 1.10 to 0.9 for four-cylinder triples. For engines with 40 to 66 in. stroke: 0.75 to 0.6 for three-cylinder triples; 0.9 to 0.7 for four-cyclinder triples; and 0.9 to 0.7 for quadruples. For compound engines with 20 to 30 in. stroke, C may be taken as 1 to 0.85. These constants hold for engines of usual proportions but, for very light or very heavy engines, the constants may come outside of the range given.

Center of Gravity of Engines. In computing trim and stability of a vessel the center of gravity of machinery must be known. In calculating this

ELEMENTARY GEOMETRY AND MENSURATION

GEOMETRICAL THEOREMS

(For geometrical constructions, see p. 101)

Right Triangles. $a^2 + b^2 = c^2$. (See Fig. 1). $\angle A + \angle B = 90°$. $p^2 = mn$. $a^2 = mc$. $b^2 = nc$. See also p. 105 and p. 132.

Oblique Triangles. (See also pp. 105, 134.) Sum of angles = 180°. An exterior angle = sum of the two opposite interior angles. (Fig. 1.)

The medians, joining each vertex with the middle point of the opposite side, meet in the center of gravity G (Fig. 2), which trisects each median.

The altitudes meet in a point called the **orthocenter**, O.

The perpendiculars erected at the midpoints of the sides meet in a point C, the center of the circumscribed circle. [In any triangle G, O, and C lie in line, and G is two-thirds of the way from O to C.]

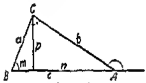

FIG. 1.

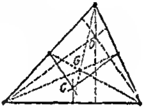

FIG. 2.

The bisectors of the angles meet in the center of the inscribed circle (Fig. 3).

The largest side of a triangle is opposite the largest angle; it is less than the sum of the other two sides, and greater than their difference

FIG. 3.

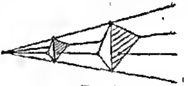

FIG. 4.

Similar Figures. Any two similar figures, in a plane or in space, can be placed in "perspective," that is, so that straight lines joining corresponding points of the two figures will pass through a common point (Fig. 4). That is, of two similar figures, one is merely an enlargement of the other. Assume that each length in one figure is k times the corresponding length in the other; then each area in the first figure is k^2 times the corresponding area in the second, and each volume in the first figure is k^3 times the corresponding volume in the second. If two lines are cut by a set of parallel lines (or parallel planes), the corresponding segments are proportional.

The Circle. (See also pp. 106, 137.) An angle inscribed in a semicircle is a right angle (Fig. 5). An angle inscribed in a circle, or an angle between a chord and a tangent, is measured by half the intercepted arc (Fig. 6). An angle formed by any two lines which meet a circle is measured by half the sum or half the difference of the intercepted arcs, according as the point of intersection of the lines lies inside (Fig. 7) or outside the circle (Fig. 8).

A tangent is perpendicular to the radius drawn to the point of contact.

If a variable line through A (Figs. 9 and 10) cuts a circle in P and Q, then

$\overline{AP} \times \overline{AQ}$ is constant; in particular, if A is an external point, $\overline{AP} \times \overline{AQ} = \overline{AT}^2$, where AT is the tangent from A.

FIG. 5.

FIG. 6.

FIG. 7.

FIG. 8.

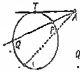

FIG. 9.

FIG. 10.

The radical axis (Fig. 11) of two circles is a straight line such that the tangents drawn from any point of this line to the two circles are of equal length. If the two circles intersect, the radical axis passes through their points of intersection. In any case, the radical axis bisects the common tangents of the two circles. The three radical axes of a set of three circles meet in a common point. (For equations, see p. 137.)

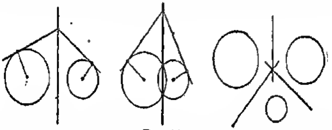

FIG. 11.

Dihedral Angles. The dihedral angle between two planes is measured by a plane angle formed by two lines, one in each plane, perpendicular to the edge (Fig. 12). (For solid angles, see p. 110.)

In a **tetrahedron,** or triangular pyramid, the four medians, joining each vertex with the center of gravity of the opposite face, meet in a point, the center of gravity of the tetrahedron; this point is ¾ of the way from any vertex to the center of gravity of the opposite face. The four perpendiculars erected at the circumcenters of the four faces meet in a point, the center of the circumscribed sphere. The four altitudes meet in a point called the orthocenter of the tetrahedron. The planes bisecting the six dihedral angles meet in a point, the center of the inscribed sphere.

FIG. 12.

FIG. 13.

FIG. 14.

FIG. 15.

FIG. 16.

FIG. 17.

Regular Polyhedra (see also p. 110): Regular tetrahedron (Fig. 13), bounded by four equilateral triangles; cube (Fig. 14), bounded by six squares; octahedron (Fig. 15), bounded by eight equilateral triangles; dodecahedron (Fig. 16), bounded by twelve regular pentagons; icosahedron (Fig. 17), bounded by twenty equilateral triangles. Figs. 13–17 show how these solids can be made by cutting the surface out of paper and folding it together.

The Sphere. (See also p. 109.) If AB is a diameter, any plane perpendicular to AB cuts the sphere in a circle, of which A and B are called the poles. A great circle on the sphere is formed by a plane passing through the center. A spherical triangle is bounded by arcs of great circles (see p.

it is necessary to approximate the location of the center of gravity of the main engine. The **vertical center of gravity** of a vertical marine engine above the center of the crankshaft is approximately 1.75 times the length of stroke. The **horizontal center of gravity** aft of the center of the forward cylinder depends on the order of cylinders, but the following constants, in which D is the sum of the cylinder diameters, will be found sufficiently accurate: compounds with the high-pressure cylinder forward, about $0.5D$; three-cylinder triples with high-pressure cylinder forward and low-pressure aft, about $0.65D$; four-cylinder triples with the low-pressure cylinders on the ends, about $0.65D$; quadruples with the high-pressure cylinder forward, about $0.75D$.

Over-all Dimensions of Engines. In laying out an engine-room arrangement it is necessary to know approximately the over-all dimensions of the engine. The design of the engine affects these dimensions to a certain extent, but in general the length of each type of engine bears a fairly constant relation to the sum of the cylinder diameters, which may be designated as D, and the height bears a similarly constant relation to the length of stroke. The constants given in Table 25 represent a fair average for vertical marine engines

Table 25. Over-all Dimensions of Vertical Marine Engines
(D = sum of cylinder diameters)

Type of engine	Compound	Three-cylinder triple valves on center line	Three-cylinder triple valves at side	Four-cylinder triple	Quadruple
$\frac{\text{Length over cylinders}}{D}$	2.00	1.80	1.65	1.85	1.90
$\frac{\text{Length over bedplate}}{D}$	1.70	1.70	1.70	1.60	1.75
$\frac{\text{Height, center of shaft to top of cylinders}}{\text{Stroke}}$	5.25	4.75	4.75	4.75	4.75
$\frac{\text{Width of bedplate}}{\text{Stroke}}$	2.7 to 3.0 for all types				

Length of Engine Room. Proceeding along the same lines as above, there are certain ratios that can be used to approximate the length of the engine room for average conditions. When the machinery is amidships, the length of the engine room is approximately from 2.25 to 2.75 times the sum of the cylinder diameters; when in the stern, the length from the forward engine-room bulkhead to the after-peak bulkhead is approximately from 2.5 to 3.5 times the sum of the cylinder diameters for triple and quadruple engines. With compound engines the length of engine room is about five times the sum of the cylinder diameters.

MACHINING AND TOLERANCES

The allowances and limitations given below are based on good American practice for merchant marine engines.

Table 1. Nozzle Coefficient Correction for Over- or Underexpansion

	Underexpanding					Overexpanding				
d = nozzle deviation...	−40	−30	−20	−10	0	+10	+15	+20	+25	+30
Velocity coef factor....	0.964	0.977	0.989	0.997	1.00	0.997	0.993	0.984	0.965	0.933

should be the same as that entering if conditions were ideal. Actually there are friction and turbulence in this passage and the result is a loss that appears as a diminution of exit velocity and a gain in enthalpy of the steam. The bucket velocity coefficients as derived from tests are given in Table 2.

Table 2. Bucket Velocity Coefficients

Velocity relative to bucket, fps..........	200	400	600	800	1,000	1,500	2,000	2,500	3,000	4,000
Velocity coef.........	*0.953*	*0.918*	*0.888*	*0.863*	*0.841*	*0.801*	*0.774*	*0.754*	*0.737*	*0.716*

Blade velocity diagrams are shown in Figs. 4 and 5. The various velocities can be calculated as outlined previously and these diagrams drawn. The work done and efficiencies obtained will be as given in *Eqs.* (1) to (13).

IMPULSE TURBINES

The total available heat drop is divided among several stages, each stage consisting of a set of nozzles and a wheel carrying a row of buckets. The velocity ratio $\rho = u/v_1$, can be made high enough to obtain good efficiency, provided v_1 can be held down. This is possible when a relatively small amount of energy is utilized in each stage. Usually the pressure drop is so subdivided that the same amount of energy is utilized in each stage. The first wheels can then be made of the same pitch diameter. Often the first stage is made with velocity compounding so as to utilize a greater portion of the energy and thereby reduce the pressure and temperature considerably. This lowers the maximum temperature and pressure to which the casing is subjected, reduces the density of the steam through which the wheel must revolve, and makes the leakage problem easier. As the steam goes through the turbine, it expands and occupies more space; consequently the pitch diameters of the last wheels are usually made larger so as to provide more area. This also results in greater blade velocity, but this is permissible in view of the lower density of steam in these stages. In the first stages the nozzles occupy only a portion of the periphery but, as progress through the turbine is made and the steam increases in volume, more and more of the periphery is used. The approximate number of stages required can be determined as follows, assuming that the pitch diameter of the blade, energy per stage, and the velocity ratio, ρ, are held constant:

$$\left(\frac{\text{Speed for single stage}}{\text{Desired speed}}\right)^2 = \text{number of pressure stages} \qquad (25)$$

Speed for single stage is the speed that would be reached if the total energy were used in one stage with the pitch diameter and velocity ratio, ρ, as decided upon.

Interior of Cylinders. The bores of cylinders and piston-valve chests should be cylindrical within the following tolerances:

From 20 to 40 in. diam. .... 0.003–0.005 in.
Larger than 40 in. diam. .... 0.005–0.008 in.
Difference in diam at top and bottom .... 0.010 in.

Cylinder Bore and Piston Clearances. Between the bore of the cylinder and the diameter of the piston and follower the clearances in inches should not be less than the following:

Diam. of cylinder, in.	H-p	I-p	L-p
21–30	0.035	0.0275	0.025
31–40	0.045	0.035	0.030
41–50	.....	0.05	0.0375
51–60	.....	0.06	0.050
61–80	.....	.....	0.065
81–100	.....	.....	0.085

Working Fits of Piston and Piston-Valve Rings. The following allowances have been found satisfactory:

Diameter, in.	Minimum, in.	Maximum, in.
12–15	0.004	0.007
16–20	0.006	0.009
21–30	0.007	0.015
31–40	0.010	0.020

Slide Valves and Seats. Working surfaces should be true planes, free from blemish and thoroughly smooth. It is advisable to plane the working surfaces of slide valves at right angles to the direction of planing of the seats.

Piston rods and valve stems should be accurately ground or machined within the following tolerances:

Tolerances on diam. plus 0.012 in. minus 0.005 in.
Deviation from exact roundness, 0.003 in.

Bearings should be accurately machined and fitted, and special care taken to secure hardness and smoothness. The following tolerances in inches are permissible:

Diam. of shaft, in.	Plus or minus in diam.	Deviation from exact roundness
6	0.005	0.0025
10	0.006	0.003
16	0.007	0.0035
Larger	0.008	0.004

Figure 8 shows a cross section through the high-pressure element of a Westinghouse marine turbine. Steam flows from right to left. The first stage has two velocity compoundings, and the succeeding stages are simple impulse. The pitch diameter of all these stages is approximately constant.

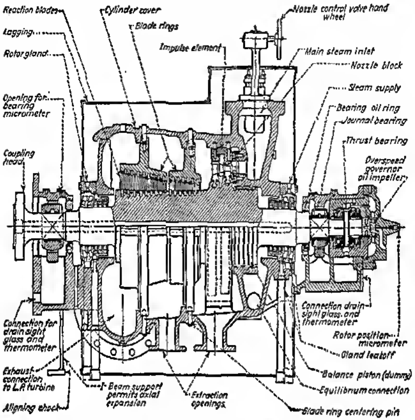

FIG. 8.—Typical cross section of a Westinghouse high-pressure turbine.

The steam exhausts from this casing into another lower pressure turbine (Fig. 9).

Rotation Loss or Windage. Experiments have shown that the rotation of the disk carrying the buckets requires energy equal to

$$L_d = \frac{143.35D^2}{\overline{V}}\left(\frac{u}{100}\right)^{2.9} \qquad \text{Btu per hr} \qquad (26)$$

and the rotation of the buckets requires energy equal to

$$L_b = \frac{638.2Dh^{1.25}}{\overline{V}}\left(\frac{u}{100}\right)^{2.8} \qquad \text{Btu per hr} \qquad (27)$$

where D = pitch diameter, ft
$\overline{V}$ = specific volume of steam, cu ft per lb
u = wheel speed at pitch diameter, fps
h = mean blade height, in.

The following clearances for **pins and journals** are considered satisfactory:

Clearance in in. for pins		Diameter, in.	Clearance in in. for journals	
Max	Min		Max	Min
0.005	0.002	5	0.005	0.0025
0.008	0.004	10	0.010	0.005
0.012	0.006	15	0.015	0.0075
0.015	0.008	20	0.020	0.010
0.018	0.010	25	0.025	0.0125

Bearing clearances in inches as follows are recommended for large engines in good alignment:

Crosshead pin brasses	0.006–0.007
Crankpin brasses	0.008–0.009
Main bearings	0.009–0.010
Eccentric straps	0.010–0.015
Crosshead slippers	0.010–0.012
Thrust shoes	0.005–0.007

Stern Bearings. Lignum-vitae must be well water-soaked before being bored out. The following clearances are permissible on **lignum-vitae bearings**:

Diam of journal, in.	Min clearance in in. for new bearings.	Wear in in. at which bearings should be renewed
8	0.050	$\frac{1}{4}$
10	0.060	$\frac{1}{4}$
12	0.075	$\frac{5}{16}$
16	0.100	$\frac{3}{8}$
20	0.125	$\frac{3}{8}$

Bearing Brasses. Sufficient clearance to permit of expansion should be allowed at the ends of the brasses where the two halves meet. Cooling water should not leak onto the bearing surface. Hollow brasses should be tested to demonstrate their ability to withstand pressure of water service.

Thrust bearings must be so fitted that all the rings perform equal duty.

Allowance for Expansion in Castings. Large iron castings subjected to steam of high temperature will expand or grow and take a permanent set. Where large cylinders are used, ample allowance for fore-and-aft expansion of the cylinders must be made in locating valve-rod guides and eccentrics.

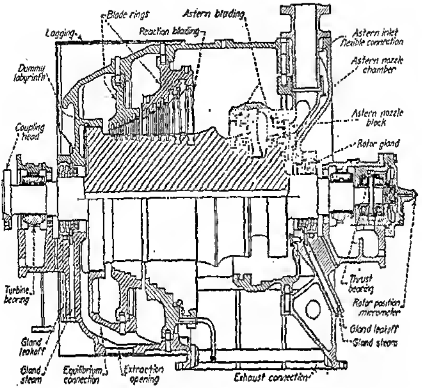

FIG. 9.—Typical cross section of a Westinghouse low-pressure turbine.

These are the losses for dry and saturated steam; for steam of other character, correct according to Table 3. For wheels above 36 in. diameter increase the losses 4 per cent above those as calculated by these formulas.

REACTION TURBINES

Referring to Fig. 5, the velocity of the steam v_1 is determined in the same manner as in the case of any nozzle except that, usually, reaction turbines are designed so that the steam leaving the moving blades of one stage enters the stationary blades of the succeeding stage at the proper angle to utilize the entering velocity. If v_2 is the leaving velocity of the preceding stage then

$$v_1 = 223.7 \sqrt{\left[\left(\frac{v_2}{223.7}\right)^2 + (h_a - h_b)\right] e_{n_s}} \text{ ft per sec} \quad (28)$$

where $h_a - h_b$ = isentropic drop through the stationary blades or nozzle
e_{n_s} = nozzle efficiency (stationary nozzle, see Figs. 5 and 10).

STEAM TURBINES

TYPES

There are three fundamental types of turbines based on the manner in which the staging or blading makes use of the energy in the steam.

1. Impulse staging, in which the steam expands or gives up part of its thermal energy in the stationary nozzles, this thermal energy being converted to kinetic energy which in turn is converted into energy in the form of speed and torque at the shaft. In the impulse stage there is no change in pressure

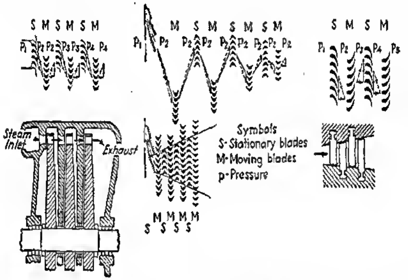

FIG. 1.—Impulse turbine with single-velocity stages. FIG. 2.—Impulse turbine with multivelocity stages. FIG. 3.—Reaction turbine.

FIGS. 1–3.—Diagrammatic illustrations of turbine elements with corresponding bucket-velocity diagrams.

in passing through the moving blade. There is a gain in thermal energy due to friction and other losses, after leaving the nozzle, known as reheat.

2. Reaction staging, in which the steam expands or gives up part of its thermal energy in the stationary nozzles and also gives up still more in the moving blades. Actually a reaction stage is a combination of impulse and reaction.

3. Velocity compound staging, in which the steam, after having part of its thermal energy converted into kinetic energy in the stationary nozzles, gives up part of this kinetic energy to one set of moving blades, then, being redirected by stationary blading or guiding devices, gives up more of the

In similar manner,

$$R_2 = 223.7 \sqrt{\left[\left(\frac{R_1}{223.7}\right)^2 + (h_{b'} - h_{b''})\right] e_{nm}} \text{ ft per sec} \quad (29)$$

where $h_{b'} - h_{b''}$ = isentropic drop through the moving blades or nozzle
e_{nm} = nozzle efficiency (moving nozzle, see Figs. 5 and 10)

TURBINE LOSSES

The losses in a steam turbine are as follows (see Fig. 11):

1. Leakage of Steam. In a single-stage impulse turbine there should be no leakage because all the steam goes through the nozzles and thereby is immediately brought to exhaust pressure. However, in multistage turbines, the steam from one stage enters a nozzle or nozzles at the exit of that stage and expands to the next lower stage. Naturally, both wheels of these two stages are carried on the same shaft. These two stages, therefore, must be separated by a wall or diaphragm, which, where it approaches the shaft, must have a packing arrangement or stuffing box because there is relative motion at that point. Therefore, there will be a tendency toward leakage at that point and steam will go through there instead of through the nozzle or nozzles, the resultant energy being lost. This loss may be as much as 5 per cent of the available energy.

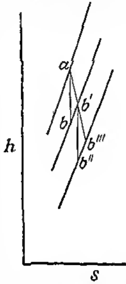

FIG. 10.—Condition of steam passing through reaction blading. b is condition leaving stationary and entering moving blades.

2. Nozzle Losses. As explained on p. 1184, there are frictional resistance and turbulence in the nozzle, resulting in a loss of 3 to 13 per cent of the available energy.

3. Blade Loss. Owing to the friction and turbulence in the blade passage there is a loss. Also there is a leaving loss due to the exit velocity of the steam from the blades. The total is 10 to 25 per cent of the available energy.

4. Windage Losses. The wheel of the turbine containing the blades rotates in an enveloping mass of dead or relatively motionless steam at the pressure and density of the steam leaving the blades. The churning of this steam requires energy, and torque at the shaft is reduced thereby. Fortunately, the largest blades and the largest diameter wheels are at the lower stages where the steam density is lower. These losses range from 2 to 7 percent of the available energy.

5. Mechanical Losses. These are due to friction of the bearings and to any load of accessories such as oil pumps and governors that may be driven from the main shaft. These losses should amount to not more than 2 per cent of the available energy.

kinetic energy to another set (or the same set) of moving blades, and so on to another and another. The velocity compounded stage is a special case of the impulse, and there is no change in pressure once the steam has left the stationary nozzles. There is the gain in thermal energy (reheat) as in the impulse stage. Simple impulse is velocity compounding with one set of moving blades instead of several or redirection.

Multistage turbines are composed of a number of stages and all three types of staging may exist or be incorporated in one turbine.

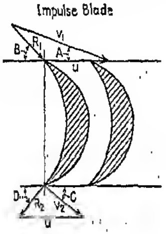

FIG. 4.

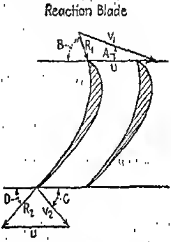

FIG. 5.

The velocity and direction of the steam through the blades are shown in Figs. 4 and 5 where the following symbols are used. All velocities are in feet per second, enthalpies in Btu per pound.

v_1 = absolute velocity of jet at blade entrance
v_2 = absolute velocity of jet at blade exit
R_1 = relative velocity of jet at blade entrance
R_2 = relative velocity of jet at blade exit
u = peripheral velocity of blade
h_1 = enthalpy at blade entrance
h_2 = enthalpy at blade exit
w = weight of steam passing, lb per sec

The work done on the blade is

$$W_b = \frac{w[(v_1^2 - v_2^2) - (R_1^2 - R_2^2)]}{50,000} \quad \text{Btu per sec} \qquad (1)$$

or

$$W_b = \frac{w}{g}(v_1 \cos A - v_2 \cos C)u \quad \text{ft-lb per sec} \qquad (2)$$

or

$$W_b = \frac{w}{g}(R_1 \cos B + R_2 \cos D)u \quad \text{ft-lb per sec} \qquad (3)$$

The force on the blade is

$$F_b = \frac{w}{g}(v_1 \cos A - v_2 \cos C) \quad \text{lb} \qquad (4)$$

or

$$F_b = \frac{w}{g}(R_1 \cos B + R_2 \cos D) \quad \text{lb} \qquad (5)$$

6. Radiation from Casing. This loss is usually so small that it can be ignored.

Turbine Efficiency. There are three types of efficiency generally considered.

1. *Thermal efficiency* is the ratio of the turbine output to the difference between the energy in the steam at the throttle and the energy in the liquid water at exhaust pressure. Figure 7 shows a temperature-entropy diagram. If h_a is the enthalpy at a, h_b the enthalpy at b, and h_c the enthalpy at c, then if P is the output at the turbine shaft in Btu, thermal efficiency is

$$E_{\text{thermal}} = \frac{P}{h_a - h_c} \qquad (30)$$

The logic behind this definition is that $h_a - h_c$ is the amount of energy that must be put into each pound of steam by the boilers. A reference to

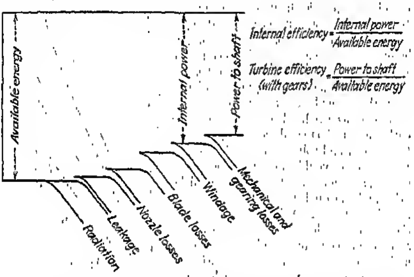

FIG. 11.

the diagram will make this clear. Assuming that the feed water enters the boilers at condition c, this must first be raised in temperature to condition d, then evaporated to condition e, and finally superheated to condition a, under which condition it enters the throttle. In short, the total amount of energy that must be supplied to the turbine per pound of steam is $h_a - h_c$.

2. *Engine efficiency* or turbine efficiency is the ratio of the turbine output to the energy available to the turbine. In Fig. 7 the energy $h_b - h_c$ all goes into the sea water used in the condenser. There is no way known to man at the present time of converting heat of condensation into mechanical power. A turbine that is 100 per cent efficient would exhaust under condition b. Therefore, the total energy available to the turbine is $h_a - h_b$. The engine efficiency or turbine efficiency, therefore, is

A comparison of engine or turbine efficiency is a much more illuminating method of judging turbines as to performance than any other. A com-

The torque in foot-pounds or force acting at a 1-ft radius where r ft is the mean radius of the row of blades is

$$\text{Torque} = F_b r = \frac{w}{g}(v_1 \cos A - v_2 \cos C)r \quad \text{ft-lb} \tag{6}$$

or,

$$\text{Torque} = \frac{w}{g}(R_1 \cos B + R_2 \cos D)r \quad \text{ft-lb} \tag{7}$$

In the case of **impulse staging only** the blade efficiency is

$$e_{ib} = \frac{2u(R_1 \cos B + R_2 \cos B)}{v_1^2} \quad \text{where } B = D \tag{8}$$

taking $\rho = \frac{u}{v_1}$ as the ratio of the blade velocity to the jet velocity

$$e_{ib} = (2\rho \cos A - 2\rho^2)\left(1 + \frac{R_2}{R_1}\right) \tag{9}$$

The optimum value for ρ or value for maximum blade efficiency is

$$\rho = \frac{\cos A}{2} \tag{10}$$

This is true regardless of the relative values of R_1 and R_2. R_2 is always less than R_1 in the case of impulse blading on account of friction loss (see p. 1190). The maximum possible blade efficiency is

$$e_{ib\,\max} = \left(\frac{\cos^2 A}{2}\right)\left(1 + \frac{R_2}{R_1}\right) \tag{11}$$

In the case of **reaction staging only** no simple and general expression for efficiency can be derived because of the varying proportions of the available energy converted to kinetic energy in the stationary nozzle and the moving blades. However, as regards the optimum velocity ratio ρ, when approximately the same amount of energy is used in both stationary and in moving blades (or nozzles)

$$\rho = \cos A \tag{12}$$

This means that, in general, the blade speed, u, must be twice as fast in the case of a reaction stage as with an impulse stage. There is no appreciable difference in efficiency.

In the case of **velocity compounding** the velocity ratio can efficiently be much lower than either impulse or reaction staging. If q is the number of compoundings or number of times the steam is redirected then

$$\rho = \frac{\cos A}{2q} \tag{13}$$

for maximum efficiency with **symmetrical and frictionless blades.** Actually, there is always some friction and, as a consequence, the velocity ratio for optimum efficiency is somewhat lower.

Comparison of Impulse and Reaction Turbines. Since there is no pressure drop across the impulse blade, there is little tendency for leakage of steam over the tip of the blade. In the first stage there should be no leak-

parison of water rates, *i.e.*, the pounds of steam per horsepower-hour, does *not* mean much unless throttle and exhaust conditions are known.

3. *Internal efficiency* is the ratio of the energy delivered to the blades to the energy available to the turbine. It corresponds to the "indicated efficiency" of a reciprocating engine. Internal horsepower is equal to power output plus bearing friction losses plus any power used to drive pumps, governors, etc. Therefore, internal efficiency is

$$E_{\text{int}} = \frac{P_{\text{int}}}{h_a - h_b} \tag{32}$$

P_{int} must be in Btu per pound of steam (see Fig. 11).

Reheat. All the internal losses that occur in any stage of a turbine, *i.e.*, those losses occurring before the net power is delivered to the blades, produce friction and turbulence in the steam and thereby reduce the final power delivered. If the negligible amount of heat that might be *transferred out through the casing is* ignored, all these losses are absorbed by the steam itself. This results in more heat in the steam at the exhaust pressure of this stage than would exist if isentropic expansion had occurred. Therefore, since the enthalpy has increased (at this pressure), the entropy and volume will also be greater. If the steam would have been wet under isentropic conditions, the steam would be drier and the quality improved under the actual *conditions. This excess of heat in* the steam at exhaust over and above the amount of heat that would have existed under conditions of isentropic expansion to the same exhaust pressure is called the reheat or RH of that stage.

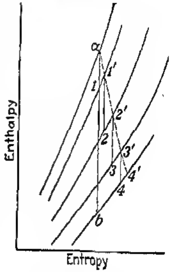

FIG. 12.

Reheat in any one stage means that less energy has been delivered to the blades in that stage and that more energy is thereby available in the next stage. In Fig. 12, suppose the steam to enter the stage under condition a. If isentropic expansion took place, it would exhaust under condition 1. However, since there are losses and since these losses reheat the steam, it actually exhausts under condition 1′, which is at the same pressure but with more heat content. The reheat RH_1 of this first stage is

$$RH_1 = h_1' - h_1$$

If this action is continued through the several stages of the turbine, the path followed by the steam will be as shown on Fig. 12 from a to 1′ to 2′, etc. From this it can readily be seen that, whereas if the whole expansion had been isentropic, the available energy would have been $h_a - h_b$, on account of the losses and reheat the actual available energy was

$$(h_a - h_1) + (h_1' - h_2) + (h_2' - h_3) + (h_3' - h_4)$$

age at all. In the other stages the predominant leakage is usually between the shaft and the diaphragm or sheet separating the stages. In reaction turbines, leakage may be seriously great if the clearance space between the blade tips and casing is an appreciable percentage of the blade length. This is true in the upper or higher pressure stages where the blades are short. In the lower stages where the blades are longer this leakage may be negligible. Tip leakage can be reduced by placing a soft metal shroud over the tips, thereby reducing the clearance to a value lower than would be tolerated for blades alone. In the event of accidental contact, the soft metal will wear away with little consequential damage.

In reaction turbines, owing to the very nature of the action, *i.e.*, pressure drop across the moving blade, it is necessary to have full peripheral entry of steam all around the wheel. The impulse stage has the advantage that stationary nozzles may occupy only a portion of the periphery permitting more liberal design and also permitting economical control by cutting nozzles in and out as the load changes. However, the efficiency increases as more of the perimeter is used. This is due to the greater windage loss of idle blades and also to the necessity of accelerating the idle or stagnant steam riding between the blades between nozzle areas or active zones.

Fairly economical control can be obtained in the case of full peripheral entry (reaction turbines) by by-passing some stages at light loads.

In view of the higher velocity ratio necessary in the case of reaction staging, the enthalpy drop per stage for a given turbine rpm, is much lower for reaction staging. Therefore, more reaction stages than impulse stages are necessary, all other things being equal—approximately twice as many.

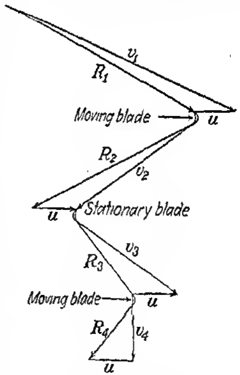

FIG. 6.—Velocity compounding (compounded twice).

Generally, the very first stage is made with velocity compounding as this permits of a still greater enthalpy drop than does simple impulse (Fig. 6). The advantage of this is that when high-pressure high-temperature throttle steam is used the high temperature can be fairly well disposed of in the nozzles of the first stage. This permits of assembling the throttle, steam chest, and first nozzle block separately or not integral with the main turbine casing and thereby obviating the necessity of subjecting the casing to the initial drastic steam conditions.

Capacity of a turbine depends upon the throttle and exhaust conditions and upon the weight of steam passed within a unit time. This latter depends upon the volume of the steam and the area of the path. Since condenser

This sum is invariably greater than $h_a - h_5$ because, as will be disclosed by an inspection of a Mollier diagram of steam, there is a continuing divergence of the constant-pressure curves as the heat content increases. In other words, these curves spread as the enthalpy and entropy increase.

Since the sum is greater than $h_a - h_b$, if the sum is divided by $h_a - h_b$, a factor is obtained by which the apparent available energy is multiplied to obtain the actual available energy. This factor is called the reheat factor or RF.

$$\text{RF} = \frac{(h_a - h_1) + (h_1' - h_2) + (h_2' - h_3) + (h_3' - h_4)}{(h_a - h_b)}$$

and this may run anywhere from unity to 1.1. In a single-stage turbine, the RF would, of course, be unity.

In any turbine the stage efficiency e_s is the ratio of energy delivered to the blades to that available in that stage. For example, in a single-stage turbine, the stage efficiency e_s is equal to the internal efficiency E_{int}. However, for a multistage turbine, the internal efficiency is greater than the stage efficiency because reheat increases the actual energy available. Therefore,

$$E_{int} = \text{RF}e_s \qquad \text{for any turbine} \qquad (33)$$

The impression should not be gained from the foregoing that, since reheat is always available in the next stage, stage efficiency is of no importance because the losses are always available for more work. It should be remembered that there is no opportunity to use any of the reheat in the last stage.

CONDITION CURVE

The path the steam takes in going through the turbine such as shown in Fig. 12 is called the condition curve. The condition curves show the character of the steam in various stages of the turbine, and this permits intelligent selection of materials for use at these points and furnishes information for extraction points for feed-water heating and gland sealing. It is best to obtain condition curves from the manufacturer as he has the most detailed and reliable information. However, when this is not available, a curve can be approximated as follows.

Suppose it is desired to determine the condition curve for a 4,000-shp turbine, receiving throttle steam at 455 psia, 740 F, and exhausting at 1.5 in. Hg abs. Plot initial point a on a Mollier diagram (Fig. 13). Assume 3½ percent pressure drop through the throttle or 16 psi. This is a constant enthalpy process, there being no gain or loss of heat; therefore, in the steam chest the pressure would be 439 psia and the condition shown as point b on the diagram. From Fig. 14 it is seen that the combined efficiency of a 4,000-shp turbine should be 73 per cent. From Fig. 3 (p. 1443), full-load gear efficiency is 96.8 per cent. $\dfrac{100 \times 0.73}{0.968} = 75.5$ per cent engine efficiency of turbine alone. From Fig. 15 it is seen that the mechanical loss for a 4,000-shp turbine is 2.25 per cent. $75.5 + 2.25 = 77.75$ per cent internal efficiency of the turbine. The isentropic drop from 455 psia, 740 F to 1.5 in. Hg abs is 480 Btu per lb (see Fig. 13 point c).

$$480 \times 0.7775 = 374 \quad \text{Btu per lb actual heat drop}$$

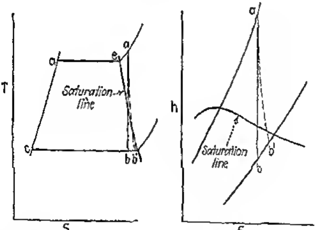
pressure in modern marine installations varies little from 1.5 in. Hg abs. the area of path or the area of annulus of the last row of blades together with throttle conditions is a measure of capacity.

General Advantage of Steam Turbines. Compared with other marine prime movers such as diesel engines or reciprocating steam engines, the turbine occupies less space, is lighter, requires less attention, has lower lubricating oil consumption, no lubricating oil in the exhaust (not a disadvantage as compared with diesel), less vibration, uniform torque, no rubbing parts except bearings, great overload capacity, great reliability, lower maintenance, and, what is perhaps most important of all considering fuel economy, the ability to use steam of higher pressure and temperature at the throttle and to exhaust to lower pressure than any reciprocating steam engine. In the sizes used for ship propulsion the efficiency of the turbine surpasses that of the reciprocating steam engine. Single units can be built in greater capacity than can any other type. The cost is much less. Turbines have the disadvantage of being inherently high-speed machines whereas a ship's propeller is inherently a slow-speed device. This necessitates the interposition of some system of speed reduction such as gearing or electric drive. Also, the turbine, requiring close clearances and relatively fine workmanship, cannot be built in so many plants as can the not so finely constructed reciprocating steam engine.

STEAM FLOW

Nozzles. The velocity of steam leaving a nozzle is

$$v = 223.7\sqrt{(h_a - h_b)e_n} \quad \text{ft per sec} \qquad (14)$$



Temperature-Entropy Diagram Mollier Diagram

FIG. 7.

where e_n = nozzle efficiency

$$e_n = \frac{h_a - h_b'}{h_a - h_b} \qquad \text{(see Fig. 7)} \qquad (15)$$

where $e_n = \dfrac{\text{actual gain in kinetic energy in actual nozzle}}{\text{calculated gain in kinetic energy in ideal nozzle}}$

Enthalpy at point a is 1381.6 Btu per lb.

$$1381.6 - 374 = 1007.6. \quad \text{Btu lb in exhaust}$$

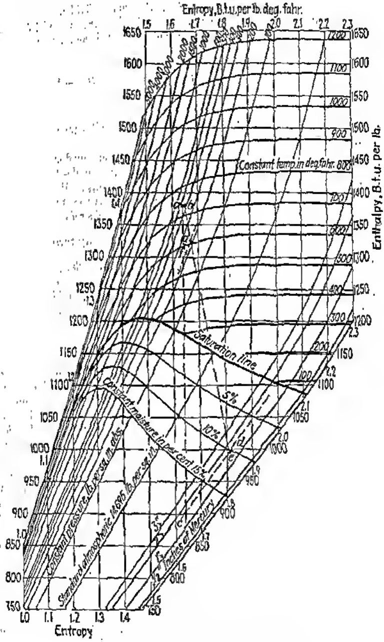


Fig. 13.—Turbine-steam condition curve.

This is the point d at 1.5 in. Hg shown on Fig. 13. In ordinary designs, the steam leaves the blades in the last stage at approximately 700 fps or with an

In well-designed nozzles c_n varies from 0.90 to 1.00 for discharge velocities not greater than 2,000 fps.
Where c_v is the velocity coefficient,

$$c_v = \frac{\text{actual discharge velocity measured by impulse or reaction}}{\text{calculated ideal velocity}}$$

$$c_n = c_v^2 \tag{16}$$

For a given weight of steam passed per second, w, the area at any point, x, in the nozzle in square feet is

$$A_x = \frac{wV_x}{v_x} \tag{17}$$

where V_x is the specific volume of the steam at point x.

If the passage areas are calculated, it will be found that for ordinary pressures at the entrance and exhausting at something less than half this pressure the areas will first decrease in magnitude, *i.e.*, the nozzle is convergent; then, as the discharge is approached, the areas increase in magnitude and the nozzle becomes divergent.

The reason for this is that, at first, the velocity increases faster than does the specific volume but, later, the specific volume increases faster than does the velocity. If the exhaust pressure is not made low enough to permit the latter situation, the nozzle will consist of only the converging portion and will be a *convergent* nozzle. Practically all loss occurs in the divergent position.

The pressure at the point where the area of the nozzle is a minimum is known as the **critical pressure**, and the corresponding velocity is the critical velocity. The ratio of the critical pressure to the initial pressure is

$$\frac{p_t}{p_a} = \left(\frac{2}{n+1}\right)^{\left(\frac{n}{n-1}\right)} \tag{18}$$

where n = exponent in the relationship

$$PV^n = \text{a constant} \qquad \text{(see p. 315)}$$

The *weight of steam*, w, in pounds per second that will flow under ideal conditions, *i.e.*, no friction, or with a discharge coefficient, C_d, of unity is

$$w = 0.668A_b\sqrt{\frac{n}{n-1}\frac{p_a}{\overline{V}_a}\left[\left(\frac{p_b}{p_a}\right)^{\frac{2}{n}} - \left(\frac{p_b}{p_a}\right)^{\frac{n+1}{n}}\right]} \tag{19}$$

where A_b = area at discharge of nozzle be it converging or diverging, sq in.
$\overline{V}_a$ = cu ft per lb steam
p_a = initial pressure, psia
p_b = exit pressure, psia

Obviously the weight of steam flowing is governed by the minimum nozzle area and, since the minimum area in a converging-diverging nozzle is at the throat or critical point, any discharge or exit pressure lower than the critical will have no effect on the weight of steam discharged. In short, the weight discharged with a discharge pressure equal to the critical is not increased

energy of approximately 10 Btu per lb which would be available in the following stage if there were one. Therefore, the condition curve should reach point e, 10 Btu below d, then jump to d. The steam does not take exactly a straight-line path in going from b to e on account of the different efficiencies of the various types of stages passed through, but it is approximately straight. As mentioned before, the first stage is usually velocity compounded twice, and approximately half of the total pressure is expended

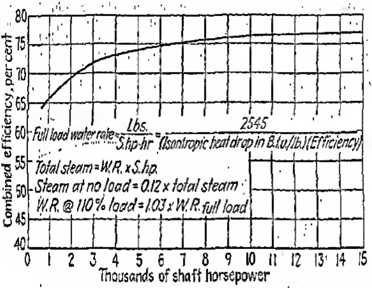

FIG. 14.—Typical combined efficiencies of marine turbines, including gears, at full load.

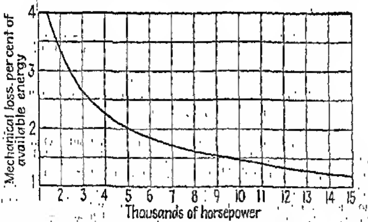

FIG. 15.—Marine-turbine mechanical losses in per cent of available energy.

in this stage. Therefore, the actual pressure in this stage would be approximately $0.50 \times 439 = 220$ psia. The isentropic drop to this pressure, b to f (see Fig. 13), would be to 1302 Btu per lb, point f. The isentropic drop is $1381.6 - 1302 = 79.6$ Btu. The efficiency for such a stage should be approximately 68 percent (see Fig. 16). Therefore, $0.68 \times 79.6 = 54.2$ Btu. $\therefore 1381.6 - 54.2 = 1327.4$ Btu per lb at 220 psia. This is point g. Draw a straight line from g to e. This is the approximate condition curve.

if the discharge pressure is lowered further. Consequently, substituting a value of $n = 1.13$, that corresponding to saturated steam, and discharge pressure equal to the critical in the foregoing equation, the result is

$$w_{sat} = 0.306A_t\sqrt{\frac{p_a}{V_a}} \qquad \text{lb per sec} \qquad (20)$$

In the same manner, if a value of $n = 1.3$, that corresponding to superheated steam, and discharge pressure equal to the critical is substituted, the result is

$$w_{supht} = 0.316A_t\sqrt{\frac{p_a}{V_a}} \qquad \text{lb per sec} \qquad (21)$$

where A_t = throat area, sq in.
p_a = initial pressure, psia
A_a = initial volume, cu ft per lb

These expressions are for steam being discharged at and below the critical pressure.

In the same manner, for steam being discharged at higher pressure than the critical,

$$w_{sat} = 1.97A_b\sqrt{\frac{p_a}{V_a}\left[\left(\frac{p_b}{p_a}\right)^{1.77} - \left(\frac{p_b}{p_a}\right)^{1.89}\right]} \qquad \text{lb per sec} \qquad (22)$$

$$w_{supht} = 1.39A_b\sqrt{\frac{p_b}{V_a}\left[\left(\frac{p_b}{p_a}\right)^{1.54} - \left(\frac{p_b}{p_a}\right)^{1.77}\right]} \qquad \text{lb per sec} \qquad (23)$$

The above weights are for steam flow under ideal conditions. Actually the steam discharge varies somewhat and the "ideal" rate must be multiplied by a discharge coefficient, C_d. C_d varies from 0.97 to 1.02 in the case of nozzles discharging at velocities of from 500 to 3,000 fps. The higher values of discharge coefficient are for wet steam said to be "supersaturated."

A nozzle that first converges and then diverges can be proportioned for only one set of initial and exhaust pressures and, at times, it is required that operation is necessary at other initial and exhaust pressures. The deviation from correct ratio for existing conditions may be expressed as

$$d = \left(\frac{r - R}{r}\right) 100 \qquad (24)$$

where R = correct exit to throat area ratio
r = actual ratio

Obviously this deviation may be positive or negative. If the exit is larger than it should be, the nozzle will overexpand the steam; if the exit is smaller, the steam will be underexpanded. The proper multiplying factor to correct for velocity is given in Table 1.

Bucket Velocity Coefficients. In impulse blading, since there is no expansion effect, the relative velocity of the steam leaving the blade passage

GENERAL DESIGN

Velocity ratio, $\rho = u/v_1$, is an important factor in the turbine efficiency. As previously mentioned, this value must be greatest to obtain maximum efficiency from a reaction stage and can be lower for simple or "one-row" impulse, and still lower for velocity compounding. The more times the velocity is compounded, the lower ρ can efficiently be. The curve (Fig. 16) shows the efficiencies to be expected at different velocity ratios for different types of blading with a nozzle angle of 20 deg. At the low-pressure end of turbines, the blade must usually be so long, sometimes nearly half the radius of the wheel, that the speeds are appreciably different from one end to the other. Since such a situation renders it difficult to satisfy all parts of the blade length with one steam velocity, the blades are made to act as impulse

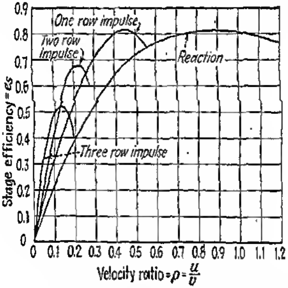

FIG. 16.—Variation of stage efficiency of turbine elements with velocity ratio—nozzle angle 20 deg.

blades at the inner end and as reaction blades at the outer end. When a high heat drop through the system (all stages) is to be contended with, it is often so difficult to reconcile blade speeds in the first stage with those in the last stage that the best solution is to divide the steam expansion into two or more separate casings. Sometimes the low-pressure casings are arranged double flow, *i.e.*, the steam enters at the center and flows toward the ends through identical sets of wheels. The high-pressure element usually is designed for higher speed than the low-pressure element. This construction lends itself well to gear drive for marine propulsion where two or more pinions of different diameter can be meshed with a single (bull) gear.

Owing to the fact that as expansion or heat drop continues below the point of saturation, liquid water appears in the steam stream. This liquid may be 15,000 times as dense as the saturated steam accompanying it in the lower stages. As a consequence, the velocity of the liquid will not be so great as that of the gas. This means that the moving blades will strike these water

134). In two polar triangles, each angle in one is the supplement of the corresponding side in the other. In two symmetrical triangles, the sides and angles of one are equal to the corresponding sides and angles of the other, but arranged in the reverse order (like right-handed and left-handed gloves).

GEOMETRICAL CONSTRUCTIONS

To Bisect a Line AB (Fig. 18). (*a*) From A and B as centers, and with equal radii, describe arcs intersecting in P and Q, and draw PQ, which will bisect AB in M.

(*b*) Lay off $AC = BD$ = approximately half of AB, and then bisect CD.

To Draw a Parallel to a Given Line l Through a Given Point A (Fig. 19). With point A as center drow an arc just touching tho line l; with any point O of the line as center, draw an oro BC with tho same rodius. Then a lino through A touching this arc will ho tho required parallel. Or, use a straight edge and triangle. Or, use a sheet of celluloid with a set of lines parallel to one edge and ahout ¼ in. apart ruled upon it.

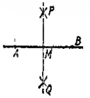

FIG. 18.

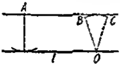

FIG. 19.

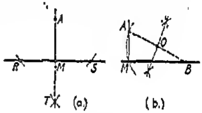

FIG. 20.

To Draw a Perpendicular to a Given Line from a Given Point A Outside the Line (Fig. 20). (*a*) With A as center, describe an arc cutting tho line in R and S, and bisect RS in M. Then M is tho foot of the perpendicular. (*b*) If A is nearly opposite one end of the line, take any point B of the line and bisect AB in O; then with O as center, and OA or OB as radius, draw an arc cutting the line in M. Or, (*c*) use a straight edge and triangle.

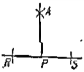

FIG. 21.

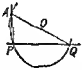

FIG. 22.

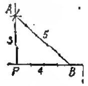

FIG. 23.

To Erect a Perpendicular to a Given Line at a Given Point P. (*a*) Lay off $PR = PS$ (Fig. 21), and with R and S as centers drow arcs intersecting at A. Then PA is the required perpendicular. (*b*) If P is near the end of the line, take any convenient point O (Fig. 22) above the line as center, and with radius OP draw an arc cutting the line in Q. Produce QO to meet the arc in A; then PA is the required perpendicular. (*c*) Lay off $PB = 4$ units of any scale (Fig. 23); from P and B as centers lay off $PA = 3$ and $BA = 5$; then APB is a right angle.

To Divide a Line AB into n Equal Parts (Fig. 24). Through A draw a line AX at any angle, and lay off n equol steps along this line. Connect the last of these divisions with B, and draw parallels through the other divi-

sions. These parallels will divide the given line into n equal parts. A similar method may be used to divide a line into parts which shall be proportional to any given numbers.

Fig. 24.

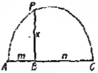

Fig. 25.

Fig. 26.

To Construct a Mean Proportional (or Geometric Mean) Between Two Lengths, m and n (Fig. 25). Lay off $AB = m$ and $BC = n$ and construct a semicircle on AC as diameter. Let the perpendicular erected at B meet the circumference at P. Then $BP = \sqrt{mn}$. (See p. 115.)

To Divide a Line AB in Extreme and Mean Ratio (the "golden section"). At one end, B, of the given line (Fig. 26), erect a perpendicular, BO, equal to half AB, and join OA. Along OA lay off $OP = OB$, and along AB lay off $AX = AP$. Then X is the required point of division; that is, $\overline{AX}^2 = AB \times BX$. Numerically, $AX = \frac{1}{2}(\sqrt{5} - 1)(AB) = 0.618(AB)$.

To Bisect an Angle AOB *(Fig. 27).* Lay off $OA = OB$. From A and B as centers, with any convenient radius, draw arcs meeting in M; then OM is the required bisector.

To draw the bisector of an angle when the vertex of the angle is not accessible (Fig. 28). Parallel to the given lines a, b, and equidistant from them, draw two lines a', b' which intersect; then bisect the angle between a' and b'.

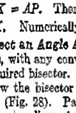

Fig. 27.

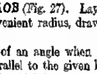

Fig. 28.

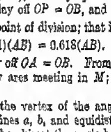

Fig. 29.

To Draw a Line Through a Given Point A and in the Direction of the Point of Intersection of Two Given Lines, when this point of intersection is inaccessible (Fig. 29). Draw any two parallel lines PQ and $P'Q'$ as in the figure; through P' draw a line parallel to PA, and through Q' draw a line parallel to QA; let these lines intersect in A', and draw the line AA'. This line AA' will (if produced) pass through the intersection of the two given lines.

To Construct, Approximately, the Length of a Circular Arc (Rankine). *In Fig. 30 draw a tangent at A. Prolong the chord BA to C, making* $AC = \frac{1}{2} AB$. With C as center, and radius CB, draw arc cutting the tangent in D. Then AD = arc AB, approximately (error about 4 min in an arc of 60 deg). Conversely, to find an arc AB on a given circle to equal a given length AD, take E one-fourth of the way from A to D, and with E as center and radius ED draw an arc cutting the circumference in B. Then arc $AB = AD$, approximately.

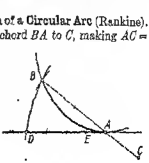

Fig. 30.

droplets if the design is such as to render smooth passage of the gas. This results in a retarding force to the blade and also a pitting of the blade. This can be minimized by shielding the inlet edges of the blades with a hard strong material such as stellite. Any amount of moisture, in the liquid state, greater than 10 per cent can be expected to cause trouble.

Rotative Speed. All other things being equal, the power of a turbine is directly proportional to its rotative speed. For this reason it is most economical from weight and cost standpoints to operate at the maximum possible low-pressure blade speeds. Blade speeds are now approaching 1,500 fps. With high speeds resulting in smaller turbines, the casing problem as regards expansion due to temperature fluctuations is eased. Also the length of time required for warming up the rotor is lessened as well as the attendant danger due to distortion from ununiform heating.

Balancing. A rotor that is of negligible length (one wheel) is in practical dynamic balance when it is in static balance (see pp. 509 and 510). When the length is of an appreciable amount, such as is the case where there are several wheels on one spindle, balancing is usually done on a balancing machine. The rotors undergoing balance must not be run at operating speed because the blading acts as fans or blowers and too much power would be involved. Dynamic balance can be obtained at low speeds provided there is sufficient force indicated to locate the point where balance weight must be added or removed. This has nothing to do with critical speed, which exists regardless of how perfectly the rotor is balanced, and is dependent on the amount of deflection of the rotor due to gravity when the rotor is at rest. Critical speed may be approximately determined by the expression

$$\text{rpm}_c = 187.7\sqrt{\frac{1}{\Delta}} \tag{34}$$

where Δ = deflection at maximum point, in.

Blading. Impulse blades, generally being in the initial stages of the turbine where the steam is superheated and thereby subject to corrosion, are usually made of corrosion-resisting material. These may either be machined from bar stock, an expensive method but justifiable when there are relatively few blades to be made, or be made from stock having a cross section similar to that desired. Long blades having change in cross section over the length are usually first forged and then finish-machined.

The material in most general use is a low-carbon stainless steel of approximately the following composition: C, 0.06 to 0.13 per cent; Cr, 11 to 13 per cent; Ni, 0.50 per cent max; Mn, 0.8 per cent max; Si, 0.50 per cent max. It should have approximately the following physical characteristics: tensile strength, 100,000 psi; minimum elongation in 2 in., 20 per cent; minimum reduction in area, 60 per cent; Brinell hardness, 200.

A chrome-nickel steel of the following characteristics is also often used: C, 0.45 per cent max; Cr, 7 per cent; Ni, 20 per cent; Mn, 0.75 per cent max; Si, 1.25 per cent max. The physical characteristics should be approximately as follows: tensile strength, 105,000 psi; max elongation in 2 in., 27 per cent; min reduction in area, 40 per cent; Brinell hardness, 200.

The common types of root fastenings are shown in Fig. 17.

Reaction blades, usually at the lower end of the turbine, are usually made of copper-zinc or copper-nickel good for temperatures not exceeding 600 F but are made of stainless steel such as is used for impulse blades when reaction

Also it should not be forgotten that the success of this device depends upon the use of metals under high stress at temperatures around 1500 F. If this problem is solved for the gas turbine, the solution can be applied to the steam turbine, which would result in great improvement in this prime mover.

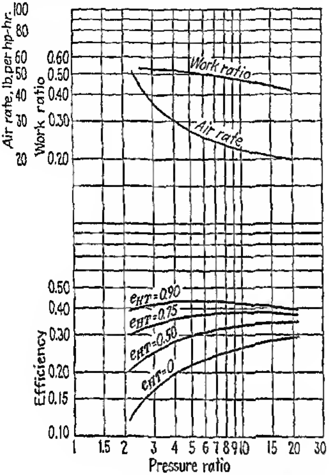

FIG. 28.—Combustion-gas turbine performance.

GOVERNING

The fundamental principles of governing are covered on p. 859. The main propulsion turbines of a ship are not governed by any device that maintains approximately constant speed as in the case of turbines driving electric generators or other auxiliaries. The load of driving the ship will prevent the propulsion turbines from overspeeding except in the event of the propeller's coming out of the water as might happen in stormy weather, or in the event of the loss of the propeller altogether. These contingencies are usually cared for by an oil-actuated overspeed device, a typical one being shown in Fig. 29. The complete assembly includes the maneuvering valves for the ahead and astern elements. Usually a guard valve is installed in series with the regular astern valve. These valves are not automatic but are hand-operated. It is good practice to place a small drain line from between the astern valve and the guard valve in order to remove the condensate, which might otherwise get into the astern blading. It is also good practice to

staging is used in the upper or higher temperature section of the turbine. Usually being long, they are sometimes made with integral spacing pieces. They may be manufactured in the same manner as are impulse blades but usually are rolled or drawn. A few standard shapes are available which are used in all designs, the design being modified to suit. The blades, both stationary and moving, are usually fastened according to the center illustration in Fig. 17. Since there is a drop in pressure across these blades, they are sometimes shrouded to permit of greater radial clearance and yet maintain low leakage.

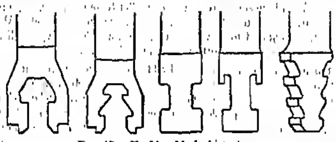

Fig. 17.—Turbine-blade fastenings.

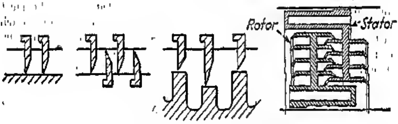

Fig. 18.—Labyrinths with radial clearance.

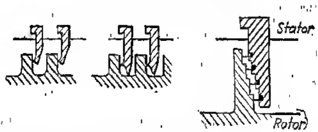

Fig. 19.—Labyrinths with axial clearance.

Leakage. To prevent steam leakage from stage to stage or to atmosphere, either carbon packings or metallic labyrinth packings are employed. In carbon packings, rings made of carbon are used in sections of 90 or 120 deg with overlapping joints at the ends and held against the shaft by means of springs. Where there is considerable difference in pressure, these rings are arranged in multiple. Labyrinths may be arranged to depend on either radial clearance (Fig. 18) or axial clearance (Fig. 19).

Dummy Pistons. In reaction turbines, since there is a pressure difference on each side of the moving blade, considerable end thrust is built up over several stages. This thrust is usually balanced by dummy pistons mounted on the rotor and running with close clearance with the casing and of the same

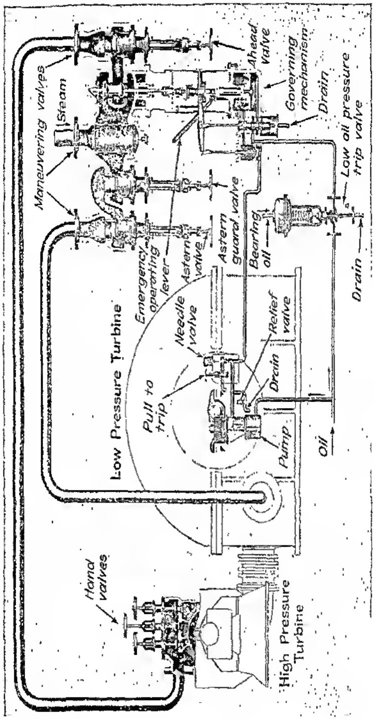

FIG. 29.—General Electric turbine governing system.

mean diameter as the steam path. This piston is then subjected to approximately the same difference of pressure as exists over the several stages so that the thrust is in the opposite direction to that due to the rows of moving blades. The result is zero thrust. The steam is led to the dummy piston by means of steam passages from front to rear, and leakage around the dummy is minimized by means of labyrinth packing (see Figs. 18 and 19).

Gland Sealing. As regards the sealing of joints where the shaft passes through the casing, the pressures run from almost throttle pressure to considerably below atmospheric. These joints are sealed by means of glands consisting of numerous rings or collars so as to provide a labyrinth (see Figs. 18 and 19). Steam condensing in this passage aids in sealing. The low-

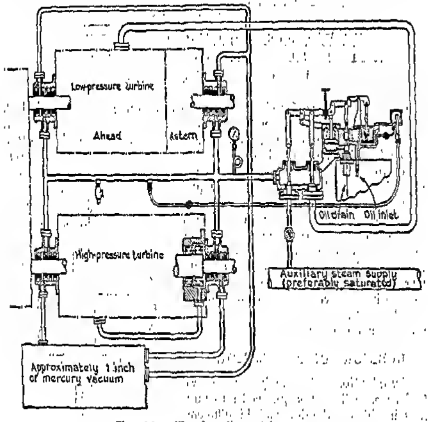

FIG. 20.—Gland sealing with steam.

pressure glands of both the straight carbon-ring and labyrinth types always have intermediate grooves that are supplied with steam under pressure higher than atmospheric. If this steam were not supplied, the air would leak into these lower stages owing to atmospheric pressure. This air would then enter the condenser and plug it up with noncondensable gas of greater amount than the air ejectors could eliminate.

However, if the intermediate grooving is supplied with steam, some of it will leak into the lower stages and be carried to the condenser, where it will condense; some of it leaking out to atmosphere. In some of the older installations, this gland leak-off steam is allowed to escape into the engine room, and the presence of this small plume of steam is an indication that the gland is properly sealed. There are two arguments against this practice:

place some hand valves at the inlet of the high-pressure turbine to permit some adjustment of the first-stage nozzle area—*i.e.*, to permit the cutting in or out of some first-stage nozzles, depending on the load.

The main propulsion-governing mechanism proper has two chief purposes: (1) to provide an upper limit to the speed of the turbines and (2) to shut off

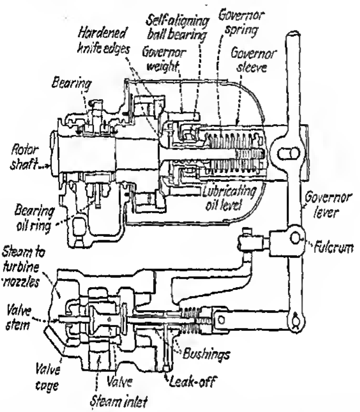

FIG. 30.—Horizontal centrifugal weight governor. This is the simplest of governors used on small turbines. It provides speed regulation suitable for pump, fan, and other mechanical drives where a single governor valve, not over 5 in. in diameter, is used. Where desired, the governor can be arranged for operation with pump or exhaust pressure control.

At three important points, friction that might impair sensitivity has been minimized in this governor. Knife edges and seats are hardened to protect against wear. Self-aligning and oil-lubricated ball bearing transmits governor movements to the valve linkage. A bushing seal around the valve stem insures freedom of valve movement.

In action, the centrifugal force of the governor weights is transmitted through knife edges and the thrust bearing to the governor lever, which operates directly on the governor valve.

A hand speed changer, adjustable while the turbine is running, can be used.

throttle steam automatically in the event of imminent failure of oil supply to bearings or gears. The operation of the system shown in Fig. 29 can be understood by studying the diagram. A positive-displacement gear-type pump is on the forward end of the low-pressure turbine shaft. It produces an oil pressure of an amount in accordance with a predetermined setting of

(1) it will fog up the engine room, impair visibility, and render conditions humid and uncomfortable; (2) it is a waste of valuable feed water.

Modern practice involves trapping this gland leak-off steam and condensing it, returning the condensate to the feed system. This will be covered more thoroughly in the section on Heat Balance, p. 1264 (see Figs. 20 and 21).

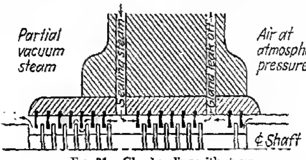

FIG. 21.—Gland sealing with steam.

The normal source for gland-sealing steam at full power is the leak-off from the high-pressure end or a tap from one of the lower stages. However, in running at reduced power, the pressure at these points may be less than atmospheric; under such circumstances, gland-sealing steam must be supplied from the exhaust line or some such reliable source. Gland-sealing steam is chargeable to the steam consumption of the turbine.

Water-sealed glands in which an impeller revolves in a pocket containing water are not in favor with some marine engineers. Complications of water supply and the hazard of a broken seal-impeller rendering the complete turbine inoperative are the reasons for this (see Fig. 22). In turbogenerator turbines, they are more acceptable.

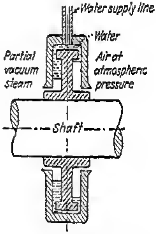

FIG. 22.—Water-sealed gland.

LUBRICATION AND BEARINGS

Lubrication is invariably of the forced-feed type. Oil is often pumped into tanks set fairly high in the ship, and this difference in head causes it to run to the turbine bearings (as well as the gearbox). Sometimes pressure from a pump is used. The bearings are of the sleeve type, babbitt-lined. The oil cools as well as lubricates the bearings and then passes through oil coolers and back to the tanks. Sensitive control devices maintain the proper level in the tanks and close the main turbine throttle in the event that the level in the tanks drops below a predetermined point.

Bearings. Small turbines may be equipped with either ball bearings or oil-ring sleeve bearings. It is considered bad practice to have both types on one turbine. Propulsion turbines usually are equipped with plain sleeve bearings lubricated by means of oil under pressure. The bearings are split and the shells made of cast iron or steel as a rule although bronze

the by-pass needle valve shown. If the speed of the turbines should exceed the desired maximum, the oil pump increases the pressure sufficiently to close the

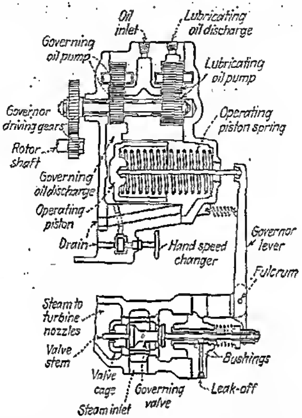

FIG. 31.—Hydraulic orifice governor. Speed adjustment over a 3:1 range is provided by this simple, positive governor for variable speed drives such as pumps, fans, and blowers. The varying pressure developed at different speeds by a gear oil pump supplies the motivating force in this governor.

The oil pressure, proportional to the square of the turbine speed, opposes a spring-loaded operating piston, which thus becomes responsive to speed changes. This piston operates the governor valve through the fulcrumed governor lever.

Increased power is provided when valve sizes exceed 5 in. in diameter, by interposing a hydraulic servomotor between the governor lever and the governor valve stem. The governor then operates only the servomotor relay, while high pressure oil supplied to the servomotor by another pump in the governor casing provides the power for operating the governor valve. The second gear pump also supplies oil under pressure to the main turbine bearings and to a reduction gear when used.

As is the case with the horizontal centrifugal governor, control by pump or exhaust pressure regulator can be used.

preemergency governor valve. In the same manner, if the lubricating-oil pressure should become low, the low-oil-pressure trip valve operates so as to close the throttle.

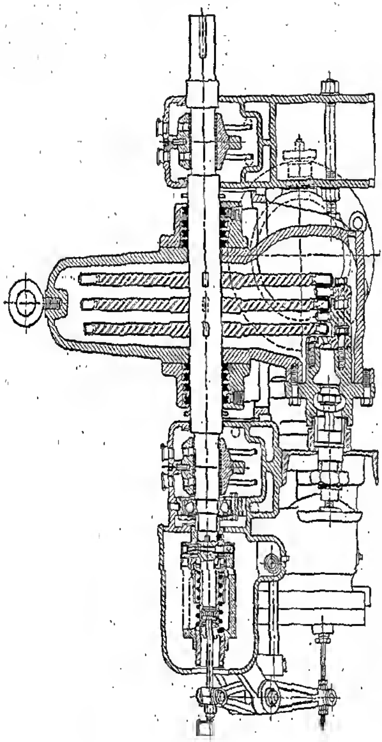

Fig. 23.—Single-stage velocity-compounded turbine. (Courtesy of Elliot Company.)

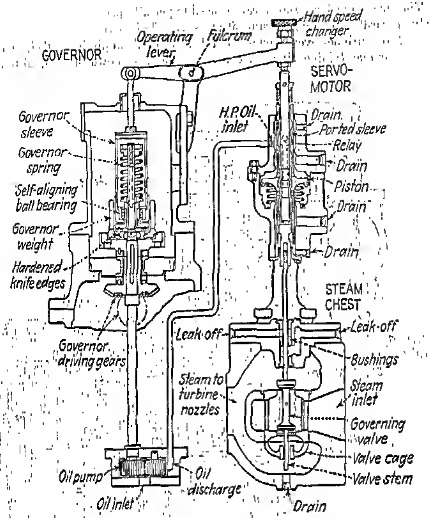

FIG. 32.—Vertical centrifugal weight governor. Powerful and positive in action, this governor, for single-valve steam chests, supplies the quality of speed regulation required for generator drive, or other machinery that must be run with small speed variation. For added power, a hydraulic servomotor is interposed between the centrifugal weight governor and the valve.

Movement of the governor weights in response to speed changes is transmitted through a ball type thrust bearing to the governor sleeve and operating lever to the servomotor relay. This relay operates within a ported sleeve integral with the operating piston, and controls the flow of high pressure oil to and from the operating cylinder. The servomotor piston is connected directly to the governor valve stem.

A gear-type oil pump at the lower end of the governor spindle supplies the high pressure oil for operating the servomotor as well as lubrication for the turbine bearings.

Either a hand or motor-operated speed changer can be used and may be adjusted while the turbine is in operation.

or brass would be better from the standpoint of anchoring the babbitt lining. Grooves are machined in the shell to help anchor the lining, and the shell is tinned and heated before the babbitt is poured. The two halves are then bolted together, and the bearing is finish-machined. Oil is furnished to the bearing at a pressure of 8 to 10 psi and a temperature of 110 to 120 F. The oil both lubricates and cools the bearing, the temperature rise of the oil being approximately 20 F. Oil seals similar to labyrinth packing are provided to prevent oil leakage or creapage along the shaft. Where high-temperature steam is used, oil leakage is a fire hazard.

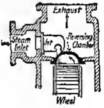

FIG. 24.—Helical-flow turbine.

Impulse turbines have some end thrust due to the axial flow of the steam through the turbine, but this is small. The dummy piston, as described previously, offsets the inherent thrust of the reaction turbine. In order to care for any remaining thrust a collar on the shaft bearing on a babbitt surface extending over the edge journal bearing is sufficient for turbines with sleeve bearings. For small turbines equipped with ball bearings, a deep-groove ball bearing or a ball-thrust bearing will suffice.

SMALL TURBINES

Small turbines for driving pumps and other auxiliary apparatus are usually made with only one pressure stage and are velocity-compounded. The most popular types at present are those shown in Figs. 23 and 24. Figure 21 shows a turbine in which the steam is redirected into moving blades twice. All through this stage the pressure is the same, but the steam continues to lose velocity as it passes through the moving wheels. Figure 22 shows a helical-flow turbine. The steam impinges tangentially on the wheel which has blades or semicircular recesses milled into its periphery, mounted around which are groups of nozzles with contiguous reversing chambers. The steam is expanded down to exhaust pressure in a single nozzle and, after striking one side of the wheel recess or blade, is reversed in direction, leaving the opposite side of the same recess or blade. This operation is repeated as many times as is necessary to reduce the kinetic energy of the steam to a relatively low value.

REHEATING

Some experimental propulsion equipment has been installed involving reheating. This is done by taking steam from the turbine at one of the lower stages, reheating it, and then returning it to the next stage. This increases the enthalpy at the given pressure and consequently increases the available energy. The steam should be removed for reheating before the saturation line is reached so that the reheating is a superheating rather than an evaporation process. Generally the steam is reheated to the original throttle temperature or thereabouts. The maximum gain is accomplished when the steam is allowed to expand and drop in temperature in the turbine until the temperature drop is approximately half the total drop that would have occurred had the steam gone to exhaust pressure in the conventional manner. Practically, it is not expedient to drop to this point because of the volume of the steam under such circumstances. Furthermore, the reheating increases this volume still further because under no circumstances should steam be

The emergency lever shown can be used to permit opening of the emergency valve regardless of the governor oil pressure. This permits operation of the propulsion turbines even though the lubricating oil supply has failed. Governors for maintaining virtually constant speed are shown in Figs. 30 to 33.

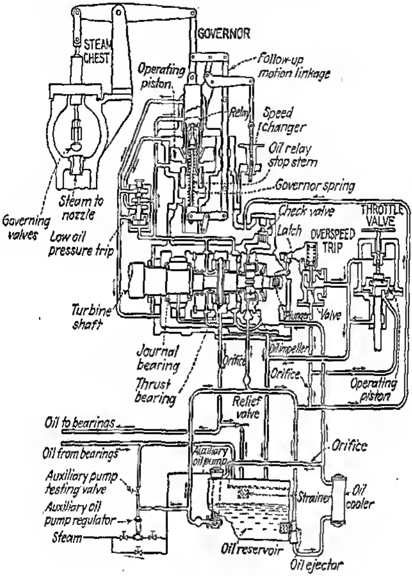

FIG. 33.—Impeller-type oil-pressure governor.

DESIGN EXAMPLE

Example. *It is desired to design one stage of an impulse turbine, the steam to enter this stage at 300 psia, 680 F; the available energy consumption or isentropic heat drop to be 30 Btu per lb steam; 50,000 lb per hr steam to be used; and the stage to run at 3,650 rpm.*

bled from the turbine for reheating unless there are a few degrees of superheat still remaining. Since the volume involved complicates an already complicated piping problem, reheating does not pay unless the throttle pressure is in excess of 1,200 lb or the temperature at throttle is approximately 1000 F. This can readily be seen by inspecting a Mollier diagram.

There are two practical ways of reheating. One is to lead the steam from the turbine into a heat exchanger, the hot side of which is receiving steam at throttle pressure and temperature from the boilers. This is known as "steam reheat" and has the advantage that the runs of large piping from turbine and return are small. The heat exchanger can be put alongside the turbine. The other method is to lead the steam from the turbine over to the boiler and through a heat exchanger across the hot side of which hot combustion gases flow. This is known as "gas reheat." This second is somewhat more economical.

In short, reheating involves relatively high throttle pressures and temperatures and increases piping complication. It has the advantage that there is a great increase in available energy and that it renders the amount of heat lost in the condenser, which is approximately the same for each pound of steam regardless of throttle conditions, a smaller percentage of the heat applied to the water as it passes through the boilers. Furthermore, a glance at a Mollier diagram will disclose that for a given throttle condition there will be less moisture in the steam at exhaust in the case of reheat than otherwise, this for a given exhaust pressure. This is a decided advantage when the turbine maintenance is considered, because moisture causes blade erosion in the lower stages. Any amount greater than 10 per cent is dangerous.

Several experimental ships, mostly with gas reheat, have been built and are operating, but no conclusive results are available yet. The problem involves mostly boiler design and piping layout. Greater economy is certainly possible with these schemes, and more research will undoubtedly be done along this line.

WATER RATES AND EFFICIENCY

The water rates of main propulsion turbines may be obtained approximately from the curve in Fig. 14. For turboelectric generators see the curve in Fig. 25. For auxiliary turbines, operating noncondensing, the turbine or "engine" efficiency can be approximated by means of the empirical expression

$$e = [10.5 + (\text{hp})^{0.46}] \left(\frac{\text{rpm}}{1{,}000}\right)^{0.43} \tag{35}$$

This holds fairly well for horsepowers from 35 to 1000. Below 35 hp the efficiency will be 5 per cent less.

ASTERN OPERATION

A steam turbine cannot be reversed unless there is some means whereby all the blades can be reversed on the wheels and all the stationary nozzles reversed. Obviously, this is extremely impractical, and no attempt is made to do it. The only alternative is to install an additional turbine with blades and nozzles arranged to obtain this torque. This is the common practice (see Figs. 9 and 34).

Reference to a Mollier diagram will disclose that with a 30 Btu per lb isentropic drop, the pressure in the stage would be 230 psia and the isentropic enthalpy 1327.7 Btu per lb. 230/300 = 0.768, therefore the nozzles would be discharging at a pressure higher than the critical and would be convergent. The efficiency of such a nozzle should be 1.00.

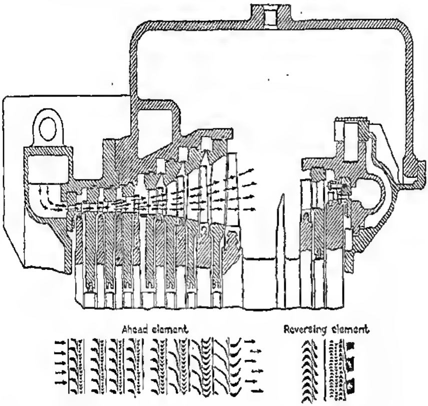

FIG. 34.—General Electric low-pressure turbine containing both impulse and reaction staging. The last two stages are reaction. Note astern turbine.

Take the discharge coefficient, C_d, as unity. Since this is superheated steam, we obtain, from Eq. (23),

$$\frac{50{,}000}{3{,}600} = 1.39A_b \sqrt{\frac{300}{2.184}[(0.768)^{1.54} - (0.768)^{1.77}]}$$

$$A_b = 4.33 \text{ sq in.}$$

where A_b = total area of all the nozzles blowing into this stage

$$v_1 = 223.7\sqrt{(h_a - h_b)e_n} = 223.7\sqrt{30} = 1{,}222 \text{ ft per sec}$$

Make the nozzle angle 20 deg. This is the angle A in Fig. 4. For maximum efficiency

$$\rho = \frac{\cos A}{2} = \frac{u}{v} = \frac{0.94}{2} = 0.47$$

$$u = 0.47 \times 1{,}222 = 575 \text{ ft per sec}$$

Required speed is 3,650 rpm. Therefore $\pi D 3{,}650 = 575 \times 60$ or $D = 3$ ft, pitch diameter of blades. Refer to Fig. 35.

Since this turbine is an additional piece of apparatus of no use in the normal operation of a ship, it is undesirable to make it any larger, heavier, or more expensive than absolutely necessary. Consequently, turbine-driven merchant ships seldom have astern power of more than 70 percent of ahead power, and some have as little as 25 percent; 40 percent is a good figure. In the case of some naval combat vessels, such as aircraft carriers where backing at certain speeds is essential to facilitate landing of planes, special considerations affect the decision as to the amount of astern power.

The astern turbine is usually in the form of several stages mounted on the low-pressure turbine shaft. The best practice is to install these reverse wheels at the exhaust or lowest pressure end. This permits the astern blading to run in steam at exhaust pressure when the ship is going ahead. This is the lowest density steam in the system and, consequently, the windage losses due to this blading are minimized. Generally, only two or three stages are

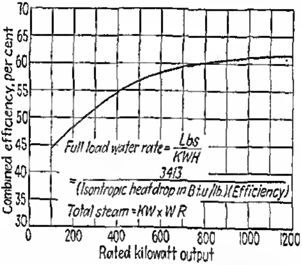

FIG. 25.—Typical combined efficiencies, including gears, of turboelectric generators at full load. Curve is for d-c generator; for alternating current, multiply by 1.02.

necessary to obtain the desired power. As in the ahead turbine, the first stage should be velocity-compounded twice, *i.e.*, the throttle steam should be brought through the nozzle and directed on one row of blades. After leaving this first row the steam should be redirected on a second row. After this the steam can be further expanded through one or two ordinary impulse stages. Reaction blading is not suited for this sort of application but has been used where tradition favors such blading.

Full-pressure and temperature steam, of course, enters the astern turbines. Consequently, with these few stages they are not very efficient. The exhaust entering the condenser is often superheated steam. This should be considered in the condenser design. Economy for astern operation is of little importance because of the short time of duration. However, unless some provision is made for ventilation steam through the ahead blading (which is seldom done), the full-power astern operation should be continued for a limited time; otherwise, the windage losses in the ahead blading may result in a detrimental temperature rise in the blading.

$$R_1 = \sqrt{u^2 + v_1^2 - 2\,uv_1 \cos A}$$

$$R_1 = \sqrt{575^2 + 1{,}222^2 - 2 \times 575 \times 1{,}222 \times 0.94} = 715 \text{ ft per sec}$$

$$R_2 = 0.875 \times 715 = 625 \text{ ft per sec (Table 2)}$$

$$\text{Cos } B = \frac{v_1 \cos A - u}{R_1} = \frac{1{,}222 \times 0.94 - 575}{715} = 0.804$$

$$B = 36.5 \text{ deg.} \qquad \text{Make} \therefore B = D.$$

The rate of doing work on the blade according to Eq. (3) is

$$W_b = \frac{W}{g}(R_1 \cos B + R_2 \cos D)u \quad \text{ft-lb per sec}$$

$$= \frac{50{,}000}{3{,}600 \times 32.2}(715 \times 0.804 + 625 \times 0.804)575$$

$$= 269{,}000 \text{ ft-lb per sec}$$

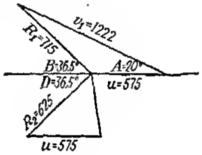

FIG. 35.

The blade efficiency is

$$e_b = \left(\frac{\cos^2 A}{2}\right)\left(1 + \frac{R_2}{R_1}\right) \tag{11}$$

$$= \frac{\overline{0.94}^2}{2} \times 1.875 = 0.83$$

The losses up to this point are nozzle losses plus blade losses; or the total efficiency to this point is 0.83 since the nozzle efficiency is considered as 1.00.

$$1 - 0.83 = 0.17 \text{ loss}$$

or

$$0.17 \times 30 = 5.1 \text{ Btu per lb}$$

Therefore, the enthalpy of the steam leaving the blades would be 1327.7 + 5.1 = 1332.8 Btu per lb at 230 psia, 228 F of superheat. Extrapolating Table 3 results in a factor of 0.60.

$$\text{Specific volume } \bar{V} = 2.727 \text{ cu ft per lb}$$

This is the character of the steam in which the wheel rotates. Use four nozzles. Total area of exit = 4.33 sq in. or 1.09 sq in. per nozzle. Make each nozzle 1.1 in square. Therefore the blades would be 1.1 in. high. If the pitch diameter is 3 ft,

$$L_d = \frac{143.35D^2}{\bar{V}}\left(\frac{u}{100}\right)^{2.9} \quad \text{Btu per hr} \tag{26}$$

$$L_d = \frac{143.35 \times \bar{3}^2}{2.727}(5.75)^{2.9} = 75{,}000 \quad \text{Btu per hr}$$

COMBUSTION-GAS TURBINE

The combustion-gas turbine is a device that uses high-temperature combustion gas at fairly high pressure as the motive fluid. When steam is used in the conventional turbine, the water must be evaporated in a boiler, but this latent heat of vaporization is not fully converted into energy in the turbine, much of it being lost in the condenser. With combustion gas, all action takes place in the superheat region, and there is no loss in a condenser. The simplest form of the cycle is shown in Fig. 26. Air is taken into a compressor at atmospheric pressure and compressed to a value of several atmospheres. Fuel is then injected and burned. The hot products of combustion then enter a turbine where expansion takes place down to atmospheric pressure. Part of the power of the turbine is used to drive the compressor, and the excess is available for ship propulsion. This is not a very efficient cycle, and it is obvious that the use of heat exchangers and reheating would give better results. Figure 27 shows a cycle that is more practical. Note that the high-pressure turbine drives only the low-pressure compressor, the useful power being delivered by the low-pressure turbine which also drives the high-pressure compressor. This is an arrangement that lends itself well to part-load operation. The efficiency of this cycle depends, to a large extent, on the amount of heat-transfer surface incorporated. On the basis of the following efficiencies and temperatures, the performance to be expected from such a cycle operating at 1500 F max is shown in Fig. 28.

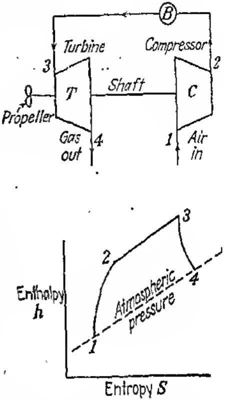

FIG. 26.—Simple combustion-gas turbine cycle.

Mechanical efficiency of turbines	0.98
Mechanical efficiency of compressors	0.98
Internal efficiency of turbines	0.90
Internal efficiency of compressors	0.85
Reheat temperature	initial turbine temperature
Inlet air temperature	70 F
Intercooler discharge temperature	90 F
Burner efficiency	0.98
Heat-transfer efficiency	$e_{ht} = \dfrac{h_5 - h_4}{h_9 - h_4}$

The air-rate and work-rate ratios are also shown in Fig. 28. Note that work-rate ratio means that if the ratio is 0.45 the plant will develop 450 useful

$$L_b = \frac{638.2Dh^{1.25}}{2{,}727}\left(\frac{u}{100}\right)^{2.8} \quad \text{Btu per hr} \tag{27}$$

$$L_b = \frac{638.2 \times 3 \times 1.1^{1.25}}{2{,}727}(5.75)^{2.8} = 125{,}000 \text{ Btu per hr}$$

Total windage loss,

$$0.60\left(\frac{75{,}000 + 125{,}000}{50{,}000}\right) = 2.4 \text{ Btu per lb}$$

Assume leakage loss as 1 percent or 0.3 Btu per lb.

$$\text{Total loss in stage} = 5.1 + 2.4 + 0.3 = 7.8 \text{ Btu per lb}$$

$$\text{Stage efficiency} = \frac{30 - 7.8}{30} = 74 \text{ per cent}$$

$$\text{Internal horsepower of this stage} = \frac{0.74 \times 30 \text{ Btu/lb} \times 50{,}000 \text{ lb/hr}}{2545 \text{ Btu/hp-hr}} = 435$$

horsepower for each 1000 hp of turbine capacity installed, the remaining 550 hp being used to drive the compressors, overcome pressure drops, etc. The higher the heat-transfer efficiency, e_{ht}, the lower the work ratio; but the difference is not great so the work ratio is shown as one approximate curve. Also the higher the heat-transfer efficiency, e_{ht}, the higher the air rate; but the difference is not great so air rate is shown as one approximate curve.

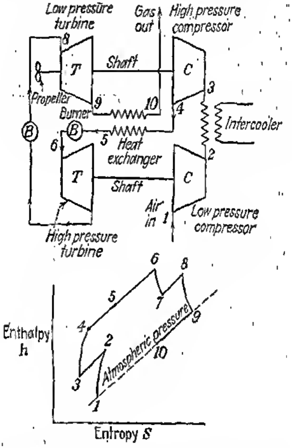

FIG. 27.—Combustion-gas turbine cycle involving heat exchangers and reheat.

From the values given it can be seen that, although the boilers, feed pumps, and other similar auxiliaries can be dispensed with if combustion-gas turbines are used, a great deal of extra heat-transfer surface must be installed as well as excess turbine capacity to say nothing of the compressors. Starting is also a problem. This can be done by means of auxiliary electric motors or diesel engines, but such a method involves units of considerable size. Therefore the practicability of such a method is questionable. Another method is to use compressed air as in the case of conventional diesel engine starting. However, it would not be necessary to have the air at more than 100 psi gage.

Astern operation presents additional difficulties. Probably electric drive is the best solution for this problem.

CONDENSATION

BY G. A. ORROK

General. Condensation is either by direct contact between steam and water, as in the case of the jet condenser; or by surface condensation, where a wall of metal prevents the mixing of the steam and the cooling medium, as in the case of the ordinary surface condenser type. The cooling medium is generally water. Direct-contact condensers may be divided into three classes: (1) jet, (2) barometric, and (3) ejector condensers. Surface condensers may be classed as (1) water-cooled, (2) air-cooled, and (3) evaporative.

In a **jet condenser**, the exhaust steam and the cooling water enter at or near the top of the condenser head and the steam is condensed by the water falling in a fine spray, the resulting mixture of condensed steam, cooling water, and air being removed by a tail pump; or an independent pump may be used to remove the air. For high vacuum, the independent air pump is necessary. The tail pump is replaced by the tail pipe in the **barometric condenser**, and the cooling water and condensed steam flow from the bottom of the tail pipe without the aid of a pump. An independent air pump is generally used, but is not necessary with some types. The **ejector condenser** acts on the same principle as a steam ejector; the exhaust steam enters the ejector through a series of orifices and is condensed by the cooling water, resulting in the water being given a velocity high enough to discharge it against atmospheric pressure.

In a **water-cooled surface condenser**, the water flows through tubes and the steam is condensed by being brought into contact with the outside of the tubes. The steam generally enters at the top of the condenser, and the cold water first passes through the lower tubes and then through the upper tubes. This is known as the counterflow type. If the condensing water enters at the top near the steam inlet, the condenser is of the parallel-flow type. Condensers are single, two, or three pass. In **air-cooled condensers**, the heat is removed from the steam by the passage of cool air through the tubes or over plates. In **evaporative condensers**, steam is brought into contact with one side of a plate or tube and water is allowed to flow over the other side. The heat which is absorbed by the water is carried away by a stream of air passing over the surface of the water, part of the water being evaporated.

Direct-contact Condensers

Condensing Water Requirements. If t_s, t_1, and t_2 are the temperatures of the steam to be condensed, of the inlet water, and of the outlet water, respectively, deg F; h_s and h_2 the enthalpys of the steam and of the outlet water at t_2, Btu per lb; W_s and W_w the weights of steam per hr to be condensed and of water per hr needed for condensing; then the ratio R of water to steam required for condensation is given by $R = W_w/W_s = (h_s - h_2)/(t_2 - t_1)$. For turbines, $h_s - h_2$ may be taken as 950 Btu; for engines 1000 Btu. Owing

To Inscribe a Hexagon in a Circle (Fig. 31). Step around the circumference with a chord equal to the radius. Or, use a 60 deg triangle.

To Circumscribe a Hexagon About a Circle (Fig. 32). Draw a chord AB equal to the radius. Bisect the arc AB in T. Draw the tangent at T (parallel to AB), meeting OA and OB in P and Q. Then draw a circle with radius OP or OQ and inscribe in it a hexagon, one side being PQ.

Fig. 31.

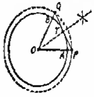

Fig. 32.

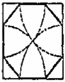

Fig. 33.

To Inscribe an Octagon in a Square (Fig. 33). From the corners as centers, and with radius equal to half the diagonal, draw four arcs, cutting the sides in eight points. The points will be the vertices of the octagon.

To Inscribe an Octagon in a Circle. Draw two perpendicular diameters, and bisect each of the quadrant arcs.

To Circumscribe an Octagon About a Circle. Draw a square about the circle, and draw the tangents to the circle at the points where the circle is cut by the diagonals of the square.

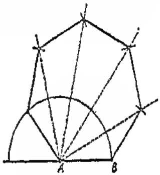

Fig. 34.

To Construct a Polygon of n Sides, One Side AB being Given (Fig. 34). With A as center and AB as radius, draw a semicircle, and divide it into n parts, of which $n - 2$ parts (counting from B) are to be used. Draw rays from A through these points of division, and complete the construction as in the figure (in which $n = 7$). Note that the center of the polygon must lie in the perpendicular bisector of each side.

To Draw a Tangent to a Circle from an external point A (Fig. 35). Bisect AC in M; with M as center and radius MC, draw arc cutting circle in P; then P is the required point of tangency.

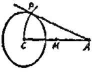

Fig. 35.

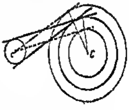

Fig. 36.

To Draw a Common Tangent to Two Given Circles (Fig. 36). Let C and c be the centers and R and r the radii ($R > r$). From C as center, draw two concentric circles with radii $R + r$ and $R - r$; draw tangents to these circles from c; then draw parallels to these lines at distance r. These parallels will be the required common tangents.

To Draw a Circle Through Three Given Points A, B, C, or to find the center of a given circular arc (Fig. 37). Draw the perpendicular bisectors of AB and BC; these will meet in the center, O.

Fig. 37.

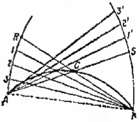

Fig. 38.

To Draw a Circular Arc Through Three Given Points When the Center is not Available (Fig. 38). With A and B as centers, and chord

AB as radius, draw arcs, cut by BC in R and by AC in S. Divide RA into n equal parts, 1, 2, 3, . . . Divide BS into the same number of equal parts, and continue these divisions at $1', 2', 3'$, . . . Connect A with $1', 2', 3'$, . . . and B with 1, 2, 3, . . . Then the points of intersection of corresponding lines will be points of the required arc. (Construction valid only when $CA = CB$.)

To Draw a Circle Through Two Given Points, A, B, and Touching a Given Line, l (Fig. 39). Let AB meet line l in C. Draw any circle through A and B, and let CT be tangent to this circle from C. Along l, lay off CP and CQ equal to CT. Then either P or Q is the required point of tangency. (Two solutions.) Note that the center of the required circle lies in the perpendicular bisector of AB.

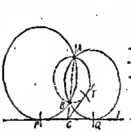

FIG. 39.

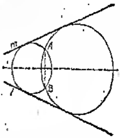

FIG. 40

To Draw a Circle Through One Given Point, A, and Touching Two Given Lines, l and m (Fig. 40). Draw the bisector of the angle between l and m, and let B be the reflection of A in this line. Then draw a circle through A and B and touching l (or m), as in preceding construction. (Two solutions.)

To Draw a Circle Touching Three Given Lines (Fig. 41). Draw the bisectors of the three angles; these will meet in the center O. (Four solutions.) The perpendiculars from O to the three lines give the points of tangency.

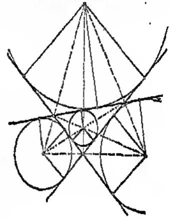

FIG. 41.

To Draw a Circle Through Two Given Points A, B, and Touching a Given Circle (Fig. 42). Draw any circle through A and B, cutting the given circle in C and D. Let AB and CD meet in E, and let ET be tangent from E to the circle just drawn. With E as center, and radius ET, draw an arc cutting the given circle in P and Q. Either P or Q is the required point of contact. (Two solutions.)

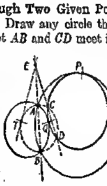

FIG. 42.

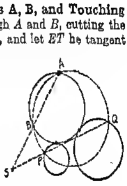

FIG. 43.

To Draw a Circle Through One Given Point, A, and Touching Two Given Circles (Fig. 43). Let S be a center of similitude for the two given circles, that is, the point of intersection of two external (or internal) common tangents. Through S draw any line cutting one circle in two points, the nearer of which shall be called P, and the other in two points, the more remote of which shall be called Q. Through A, P, Q

to the presence of air and imperfect mixing, t_h is 5 to 10 F lower than t_i. In proportioning ordinary jet and barometric condensers, W_s is the normal amount of steam to be condensed; a 50 percent overload is common at some reduction of vacuum.

Jet-condenser Design. Injection and tail pipes are usually designed for an allowable velocity of 5 fps. The steam entrance nozzle may be designed for a velocity of 300 to 600 fps. In the barometric type, the top of the tail pipe should be at least 35 ft above the hot well level. The condenser head should be as near to the exhaust flange as possible, for friction and velocity head increase rapidly with increasing vacuum. Heads of practically any shape may be used in jet and barometric types and are equally efficient if the water and steam are brought into intimate contact and the air is collected and carried away. The use of these types of condenser for power work is decreasing; in the chemical industry it is increasing, particularly the ejector type.

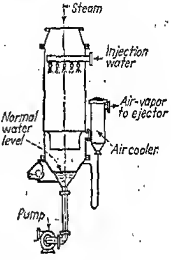

FIG. 1.—Parallel-flow Jet Condenser.

Surface Condensers

Surface Condensation. Let q be the total heat to be transmitted per hour, Btu; A the total outside surface of tubes, sq ft; W_s the steam condensed per hour, lb; W_w the condensing water required per hour, lb; $R = W_w/W_s$; U the coefficient of heat transmission, Btu per sq ft per deg F per hr; t_m the mean temperature difference of water and steam, deg F; t_s the temperature corresponding to the vacuum, deg F; t_c the hot-well temperature, deg F; t_1 and t_2 the temperature of circulating water at inlet and outlet, respectively, deg F; h_s the enthalpy, of the entering steam, Btu; h_c the enthalpy of the hot well water, Btu. Then, $q = Ut_mA = W_s(h_s - h_c)$; $W_w = W_s(h_s - h_c)/(t_2 - t_1)$; and $A = W_w(t_2 - t_1)/Ut_m = W_s(h_s - h_c)/Ut_m$. The value of U depends on the velocity of the water, the material of the tubes, the cleanliness factor, and the amount of air present. The mean temperature difference for rough calculations with small rise in temperature of the circulating water may be taken as the arithmetical mean without serious error, but for most calculations the logarithmic mean should be used. See Table 1. The water velocity in the tubes should not exceed 8 fps; and under normal condition, a velocity between 6 and 7 ft is the most economical. If the material coefficient for copper, Muntz metal, red brass, Admiralty metal, and aluminum brass is taken as unity, coefficient of 0.97 should be used

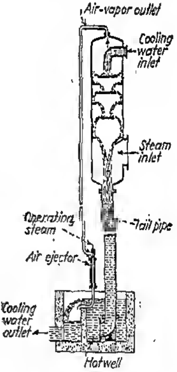

FIG. 2.—Counter-current Barometric Condenser.

Leaving temperature = 102 + 8.6 = 110.6 F.

$$\Delta_m = \frac{\Delta_{01} - \Delta_{02}}{\log_e \frac{\Delta_{01}}{\Delta_{02}}} \qquad (5)$$

Assume counter flow.

$$\Delta_m = \frac{75.4 - 8}{\log_e \frac{75.4}{8}} = 30 \text{ F}$$

Assuming that the temperature drop through the metal of the tube is negligible in so far as calculation of film temperature is concerned; also assuming that the drop through each film is approximately the same, then the film temperature should be approximately $\frac{30}{4} = 7.5$ F or 8 F higher or lower than the average water temperature or 148 − 8 = 140 F for the hot water and $\frac{102 + 110.6}{2} + 8 = 114.6$ F for the cold water.

$$h_0 = 160(1 + 0.012t_f)\frac{V_i^{0.8}}{D_i'^{0.2}} \qquad (6b)$$

$$h_i = 160(1 + 1.38)\frac{5^{0.8}}{0.527^{0.2}} = 380\frac{3.624}{0.8748} = 1{,}560$$

$$\frac{1}{UA} = \frac{1}{h_iA_i} + \frac{L}{KA_m} + \frac{1}{h_0A_0} \qquad (5a)$$

K for Admiralty metal = 64.

$$L = \frac{0.049}{12} = 0.004 \text{ ft}$$

$$\frac{1}{UA} = \frac{1}{1{,}770 \times 0.138} + \frac{0.004}{64 \times 0.153} + \frac{1}{1{,}560 \times 0.164}$$

$$\frac{1}{UA} = 0.0085$$

If A is considered as the outside area,

$$A_0 = \frac{\pi 0.625}{12} = 0.164 \text{ sq ft per ft length}$$

$$U_0 = \frac{1}{0.0085 \times 0.164} = 718 \text{ Btu/(hr) (sq ft) (deg F)}$$

$$\text{Area required} = \frac{\text{Btu per hr}}{\Delta_m U}$$

$$= \frac{3{,}400(186 - 110)}{30.0 \times 718} = 12 \text{ sq ft}$$

$$\frac{12 \text{ sq ft}}{0.164 \text{ sq ft/ft length}} = 73 \text{ ft of tubing}$$

$$\frac{3{,}400 \text{ lb/hr}}{1{,}080 \text{ lb/hr/tube}} = 2 \text{ tubes in a one-pass cooler, } \frac{73}{2} = 36.5 \text{ ft long}$$

for aluminum bronze, 0.90 for 70-30 cupronickel, and 0.84 for monel metal. The cleanliness factor varies between 0.80 and 0.90 for normally clean water, but if the water contains scale-forming ingredients a cleanliness factor of 0.70 may be assumed.

Table 1. Logarithmic Mean Temperature Difference between Steam and Condensing Water

(As given by the expression $(t_2 - t_1)/\log_e[(t_s - t_1)/(t_s - t_2)]$, where t_s is the temperature of the steam, t_1 of the injection water, and t_2 of the discharge water)

$t_2 - t_1$	$t_s - t_1$

The Heat Exchange Institute has stated the performance that may be expected from a well-designed condenser with new and clean tubes. Figure 3 shows the expected heat-transfer rates with circulation water at 70 F and for tubes of Muntz metal, Admiralty, red brass, aluminum brass, copper, or arsenical copper; with tubes of 70-30 copper-nickel, or 80-20 copper-nickel, the rates are to be reduced 10 percent. The temperature-correction curve gives correction factors for water temperatures

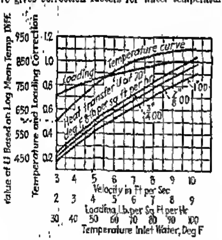

FIG. 3.—Heat-transfer Rates through Condenser Tubes (Heat Exchange Institute).

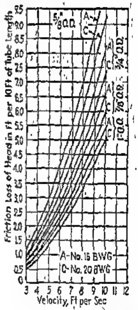

FIG. 4.—Friction Loss in Condenser Tubes (Heat Exchange Institute).

other than 70 F. The curves are for a condensation rate of 8 lb per sq ft per hr; for other rates, a correction factor is given by the load curve.

The head loss through clean condenser tubes, according to the Heat Exchange Institute, may be assumed to be as in Fig. 4. The water-box losses per pass is stated to be as follows:

Water velocity in tubes, fps	4	6	8	10
Loss of head in boxes, ft	0.63	1.13	1.72	2.4

The total condenser friction is the sum of the tube loss and the water-box losses.

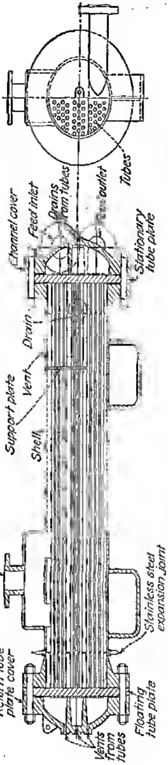

FIG. 1.—Typical section of feed-water heater. (*Courtesy of Foster Wheeler Corporation.*)

Design of Surface Condensers. (See pp. 394 and 399.) In condenser design, the given quantities usually are W_s, t_1, and the required vacuum. It is important that the place of measurement of the vacuum should be stated, and this is usually in the nozzle connecting the prime mover to the condenser. The highest vacuum will always be found at the air-pump suction, less in the body of the condenser, and the lowest vacuum in the nozzle. The vacuum inside the prime mover will be less by the velocity head necessary to give motion to the exhaust and by friction in the nozzle. The allowable velocity in a turbine nozzle is about 600 fps. The loss (or "drop") in a well-designed condenser should be less than 0.1 in. of mercury, and t_s should be taken as the temperature corresponding to this reduced vacuum. For good practice, t_2 should be 8 to 10 F lower than t_s. W_b/W_s, or the ratio of cooling water to condenser steam, usually ranges from 80 to 150 for single-pass condensers and from 50 to 90 for multipass condensers for turbine application. Single- and two-pass condensers are generally used. Single pass is used where the pumping head external to the condenser is small. Two pass is indicated for cooling tower or cooling pond installations.

Small tubes are best for the transmission of heat, but cannot be used with dirty water, so that the usual sizes are 5/8, 3/4, 7/8, and 1 in., with 7/8 in. most common. In two-pass condensers, the tube length is usually 16 to 20 ft; in single pass, 20 to 30 ft.

Surface condensers for large turbine installations have generally 0.6 to 1.5 sq ft of **condensing surface per kw**, or approximately 1/10 to 1/4 sq ft per lb of steam condensed per hr. Small turbogenerators require 2 to 4 sq ft per kw, or 1/10 to 1/8 sq ft per lb of steam per hr.

For **dry-air condensers** the coefficient of conductivity in Btu per hr per sq ft of surface per deg F difference of temperature varies from 3 in still air to 14 with air moving at a velocity of 1,500 fpm.

Materials of Construction. (See p. 632.) The materials generally used for **tubes** are Admiralty, copper, aluminum bronze, and Muntz metal. Any of these will give satisfactory service with fresh water, but with salt water (see p. 663) trouble may be experienced. Admiralty mixture (70Cu, 29Zn, 1Sn with .1 percent arsenic to prevent dezincification) aluminum bronze, and aluminum brass are generally used for salt water. Tubes are made of No. 20, No. 18, and sometimes No. 16 B. W. G. **Tube spacing** is important, as there must be room for the glands and sufficient metal between them for strength. The minimum allowable spacing or pitch of tubes is as follows (number of tubes per sq ft $= 166/s^2$, approx, s being the pitch in inches):

Diam of tube, in.	5/8	3/4	7/8	1	1 1/4
Pitch of tubes, in.	15/16	1 1/16	1 3/16	1 5/16	1 9/16
Number of tubes per sq ft	189	147	118	96	81

The **tube sheets** should be of rolled Muntz metal or Naval brass. A rolled sheet will give the best service, although cast sheets are used. Thickness should be at least 1/8 in. greater than the tube diameter but has been standardized by the Heat Exchange Institute as follows:

Area of tube sheet, sq in.	Up to 1965	1965–3739	3740–8495	8496–30791	30792 and over
Thickness, in.	7/8	1	1 1/8	1 1/4	1 1/2

Tubes are usually rolled into both inlet and outlet tube sheets, and expansion is provided for by the use of a floating head, a welded steel joint in the shell, or by bowing the tubes. The inlet tube sheet should be faced with a

Make eight pass.

$$\frac{36.5}{8} = 4.5 \text{ ft between tube sheets}$$

$$2 \times 8 = 16 \text{ tubes total}$$

$$\frac{16 \times 0.7854 \times \overline{0.625}^2}{144} = 0.0342 \text{ sq ft}$$

Cold water must run 5 fps. Average temperature is 106 F. 0.01615 cu ft per lb at this temperature.

$$\frac{30{,}000 \text{ lb/hr} \times 0.01615 \text{ cu ft/lb}}{3{,}600 \text{ sec/hr} \times 5 \text{ fps}} = 0.027 \text{ sq ft}$$

$$0.0342 + 0.027 = 0.0612 \text{ sq ft}$$

Make 16/189 = 0.0846 sq ft (see p. 1219)

Inside shell or $d = \sqrt{\frac{0.0846}{0.7854}} = 0.327$ ft or 3.93 in. Make O.D. = 4 in.

Over-all dimensions of cooler, approximately 5 ft × 4 in. containing sixteen ⅝-in. tubes arranged for eight passes.

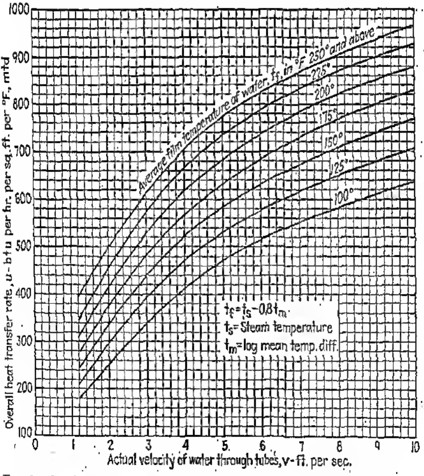

FIG. 2.—Feed-water heaters' heat-transfer rates. For 1-in. Admiralty tubes and smaller. For steel use 80 per cent of curve valve.

[b] In brass, specific gravity = 8.56.

radius tool to form a bell mouth; the flaring of the tube over this bell mouth improves the entrance condition to the tube. The hole in the tube sheet may have circumferential grooves to improve the holding power. Occasionally the inlet end is made tight by metallic packing which is preferred to fiber packing or paraffined corset lace. This is held in place by glands with rounded entrance. On the outlet side, metallic packing, without a ferrule, is often used.

Condenser shells are usually made of welded steel reinforced against collapsing pressure. Tubes should be supported at distances of 40 to 50 diam by supporting plates (usually of cast iron) drilled with clearance around the tubes. Water boxes should be large and designed to offer little resistance to the passage of the water and to provide uniform distribution of water among the tubes. Several holes, ¼ or 1 in. diam, should be provided in the *water partition of multipass condensers to permit draining* of the tubes and box and to vent excess air from the first to the last water pass. Where possible the steam should enter from the top and water at the bottom (countercurrent principle), but this is not essential, as parallel flow condensers give good results. The bottom of the circulating-water outlet should be above the highest point of the tube bank. If this cannot be done at the water box, *the discharge pipe should be carried up to the* same height away from the condenser.

The steam passage should be direct to the tube bank, and the nozzle should be spread so that no dead pockets may be left away from the path of the steam. The tube layout in a given condenser shell should be chosen so as to offer the least resistance to the steam penetration into the tube nest. The velocity of

Feed-water Heaters. Open or direct-contact feed-water heaters, being merely mixing devices, do not operate on a basis of heat transfer. Only in *closed, noncontact,* or surface heaters does a transfer of heat occur from the steam to the water. All heaters on a ship, other than the deaerating heater, are of this type and consist essentially of a number of straight or curved tubes connected at their ends to water boxes, or heads, enclosed in a shell, usually cylindrical in shape. The tubes are usually made of brass or copper

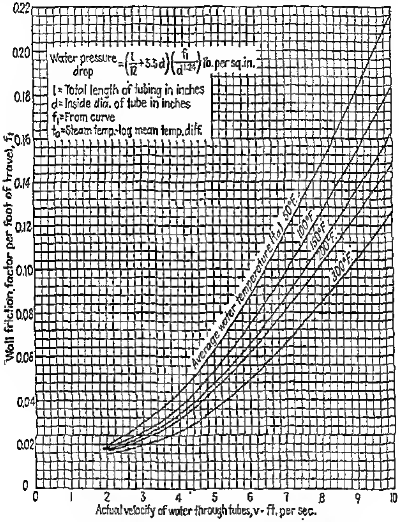

FIG. 3.—Feed-water heaters. Water friction loss.

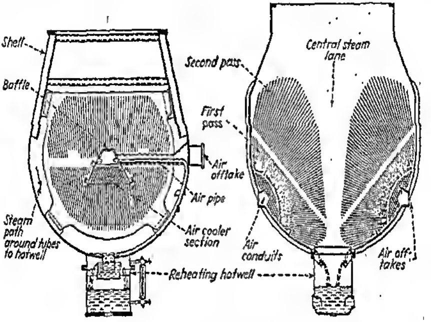
alloy in order that they may resist corrosion. The heaters may be made single pass or multipass, usually the latter in small capacities in order that an economical shape may be obtained (see Fig. 1).

Structurally, the feed-water heater resembles the condenser, especially when the heater is to use steam below atmospheric pressure. In this case the shell is under pressure tending to cause it to collapse as in the case of a condenser. The higher pressure heaters are subjected to pressures tending

steam in the nest should be kept nearly uniform, and consequently the area of passage should decrease fast at first and slower toward the air suction. The dripping condensate reduces the heat transfer, and in general the lower tubes are the least efficient. In order to provide sufficient steam entrance area, a differential spacing of tubes is used in smaller condensers, sometimes in combination with triangular shape of the tube nest. In larger condensers, steam lanes are also provided. Radial-flow condensers with steam admission on the full circumference of the nest give good results. Eccentric radial layouts of tubes are employed in many condensers built for high vacuum. It is essential that the area of the steam passage near the suction to the air pump be reduced sufficiently to provide a fair velocity of the remaining steam-air mixture, otherwise, the part of the tube nest at the end of steam path will become air bound.



Westinghouse Elliott

FIG. 5.—Surface Condensers.

Water connections should be figured for a velocity of 6 to 8 fps and the air-pump connection should be at least twice that of the hot-well pump suction, which should be figured for about 4 fps. **Air-pump connections** should be arranged to draw the air-steam mixture evenly from the end of the steam path. In high-vacuum installations, an addition of a special air cooler either inside or outside the main shell increases the efficiency of the main tube nest and permits the reduction of the bulk and weight of condenser shells. Condensers with sealed hotwells are used to reduce the oxygen content in feed water by protecting the condensate from contact with the rich part of the air-steam mixture.

AIR PUMPS

The amount of air in feed water varies from 0.75 to 5 percent by volume at atmospheric temperature and pressure. If closed heaters are used, all the air passes through the boilers and prime movers into the condenser. If open heaters are used, the air in the feed water (at 200 F) should not be over 1 percent. When deaerators are installed, the non-condensible gases

to cause the shell to explode, and they must be designed, with this in mind, to withstand such pressures. Information for the design of tube-type feed-water heaters is given in Figs. 2 and 3.

An example of the use of this information follows:

Example. Assume that it is necessary to design a feed-water heater to heat 40,000 lb per hr water from 240 to 320 F with steam entering at 1260 Btu per lb at 100 psia. Drain to leave at saturation temperature or 328 F ⅝ in. O.D. Admiralty metal tubes to be used with a maximum tube length of 12 ft. Proceed as follows:

Enthalpy of entering steam	=	1260 Btu/lb
Enthalpy of leaving drain	=	298.4
Heat transferred per lb	=	961.6 Btu/lb

Temperature of steam = 328 F

$$\Delta_m = \frac{\Delta_{01} - \Delta_{02}}{\log_e \dfrac{\Delta_{01}}{\Delta_{02}}} = \frac{88 - 8}{\log_e {}^{88}\!/_{8}} = 33.3 \text{ F} \tag{5}$$

$$t_f = t_s - 0.8t_m = 328 - 26.6 = 301.4 \text{ F}$$

Take 8 fps velocity (Fig. 2.)

$$U = 900$$

Enthalpy of feed water entering	=	208.34 Btu/lb
Enthalpy of feed water leaving	=	290.28
Transferred	=	81.94 Btu/lb

Total heat transferred = 40,000 × 81.94 = 3,277,600 Btu/hr

$$\text{Surface area} = \frac{3,277,600}{900 \times 33.3} = 109.2 \text{ sq ft}$$

Volume of water at $\frac{240 + 320}{2} = 280$ F is 0.01726 cu ft per lb.

$$(\text{lb/tube/hr})\left(\frac{0.01726}{3600}\right) = (\text{lb/tube/hr})\ (4.8 \times 10^{-6}) = (\text{cu ft/sec/tube})$$

$$\frac{(\text{Cu ft/sec/tube})}{(\text{sq ft/tube})} = \text{ft/sec}$$

$$\frac{(\text{Lb/hr water})(\text{number of passes})}{(\text{Total number of tubes})} = \text{lb/tube/hr}$$

Therefore

$$\frac{(\text{Lb/hr water})(\text{number of passes})(4.8 \times 10^{-6})}{(\text{Total number of tubes})(\text{sq ft/tube})} = v$$

$$\text{Total number of tubes} = \frac{(\text{lb/hr water})(\text{passes})(4.8 \times 10^{-6})}{v(\text{sq ft/tube})}$$

Using No. 18 B.W.G. tube, ⅝ O.D.

$$\text{I.D.} = 0.625 - 2(0.049) = 0.527$$

$$\frac{0.7854(0.527)^2}{144} = 0.001525 \text{ sq ft/tube}$$

$$\text{Total number of tubes} = \frac{(40,000)(1)(4.8 \times 10^{-6})}{8 \times 0.001525} = 15.75$$

should be less than $\frac{1}{10}$ of 1 percent. The leakage in surface condensers is an extremely variable quantity, ranging from 1 percent in tight condensers to 25 percent or more in condensers in poor condition. The average leakage is from 5 to 10 percent of the volume of the feed water. As there is always leakage through glands, pipes, or joints, the air pump must have a displacement greater than that given by the above formula. The Heat Exchange Institute specifies that the capacity of the air-removal equipment for turbines should be not less than the following quantities; for engines these quantities are to be doubled. They are expressed in cfm of free air at 70 F.

Steam condensed, lb per hr..........	5,000	10,000	20,000	40,000	75,000	100,000
Air removal capacity, cfm...........	2.20	2.65	3.00	3.65	5.00	6.5
Steam condensed, lb per hr....	150,000	250,000	350,000	450,000	600,000 and over	
Air removal capacity, cfm.....	8.5	10.0	11.5	13.5	16.0	

The volume of free air (cfm at 70 F) liberated from 1,000 gal of injection water varies with the water temperature and may be assumed to be as follows:

Injection water temp, F...............	90	80	70	60	50	40	35
Air liberated, cu ft..................	2.18	2.40	2.64	2.93	3.30	3.75	4.0

In jet or barometric condensers, the combined circulating and air pump generally has a displacement of 3 times the volume of the injection water. If an independent air pump is used, the displacement should be twice the volume of the injection water.

The **air-removal equipment** may be a reciprocating dry-vacuum pump, a "burling-water" pump (Fig. 6), or **steam-jet air ejectors** (Fig. 7). In new installations and for replacement, the steam jet has replaced other types because it has no moving parts, is relatively free from maintenance, and is usually more economical to operate. One, two, or three stages are used depending on the vacuum desired, and two or three jets in parallel can make up each stage. Two-stage ejectors are most common.

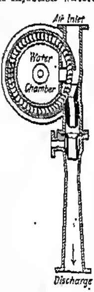


FIG. 6.—Westinghouse-Leblanc Rotary Air Pump.

Air pumps perform best when all possible vapor is condensed and removed before the air reaches the jets. The final condensing of the steam from the air-rich mixture and the cooling of the resulting saturated air-vapor mixture is accomplished either in an internal air cooler, usually a group of tubes baffled off from the main bank, or in an external air cooler. The location of the air-cooler section within the condenser, air offtake arrangement, and use of external coolers are important items of condenser design.

A single-stage ejector can be vented to atmosphere for the discharge of air and steam mixture from the jet. A two-stage ejector requires for efficient operation that first-stage steam be condensed and air-vapor mixture again cooled before passing to the second-stage jet (Figs. 8 and 9). This cooling is usually accomplished in a shell-and-tube **intercondenser** using condensate as cooling medium to recover ejector-steam heat.

An **aftercondenser** (Fig. 9) recovers heat from the final-stage steam, permits measuring air leakage, and avoids exhausting steam to atmosphere. For use in starting, when no condensate flow is available, the aftercondenser can be arranged with a separate raw-water section or a by-pass control

Call it 16 tubes for one-pass heater.

$$\text{Tube length} = \frac{\text{area of surface}}{\left(\frac{\text{number of tubes}}{\text{pass}}\right)(\text{passes})(\text{area/ft length tube})}$$

$$= \frac{109.2}{16 \times 1 \times 0.1636} = 41.8 \text{ ft for one pass}$$

For 12 ft, maximum length,

$$\frac{41.8}{12} = 3.5, \text{ call it 4 passes}$$

$$\text{Tube length} = \frac{109.2}{16 \times 4 \times 0.1636} = 10.5 \text{ ft} = \frac{l}{12}$$

Water pressure drop (see Fig. 3),

$$\left(\frac{l}{12} + 5.5d\right)\left(\frac{f_1}{d^{1.24}}\right)(\text{passes})$$

$$f_1 = 0.084 \text{ from curve}$$

$$(10.5 + 5.5 \times 0.527)\left(\frac{0.084}{0.527^{1.24}}\right)(4) = 10 \text{ psi}$$

For four passes, drop per pass in the water box at the end is 1.72 ft (see table, p. 1218).

$$\frac{4 \times 1.72}{2.3} = 3 \text{ psi}$$

$$10 + 3 = 13 \text{ psi, total drop}$$

Total number of tubes in the heater is $4 \times 16 = 64$. Taking $\frac{3}{8}$-in. clearance between tubes, the pitch for $\frac{5}{8}$-in. tubes would be $\frac{5}{8} + \frac{3}{8} = 1$ in. In any case, the number of tubes per square foot is $166/(\text{pitch})^2$ and in this case $166/1^2 = 166$ tubes per square foot.

$$\frac{64}{166} = 0.386 \text{ sq ft or } 55.5 \text{ sq in.}$$

$$\text{Diameter inside shell} = \sqrt{\frac{\text{area}}{0.7854}} = \sqrt{\frac{55.5}{0.7854}} = 8.4 \text{ in.}$$

With steam pressure at 100 psia or 85 psi gage and 1,000 psi stress allowable in the shell $t = \frac{pd}{2s} = \frac{85 \times 8.4}{2 \times 1{,}000} = 0.358$ in. would be sufficient. Make it $\frac{3}{8}$ in. The outside diameter should be $8.4 + 0.375 = 9.15$ in.

Fuel-oil Heaters. Fuel-oil heaters are, in general, very similar to closed, or noncontact, feed-water heaters in which the steam and the fluid to be heated are separated by metallic surfaces through which the heat is transferred from the steam to the fluid. There are three general types:

1. Multipass heaters, using straight or slightly curved tubes, oil inside.
2. Same as type 1 except with oil outside the tubes.
3. Heaters with the heat-transfer area consisting of flat surfaces with small sections or passages for the oil.

Type 1 is the most popular; in general, it should have not less than four passes. Type 2 is in disfavor, probably because the low velocity of the oil in the shell and the dependence on convection retard heat transfer. Type 3 is

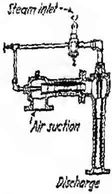

FIG. 7.—Two-stage Steam-jet Air Ejector.

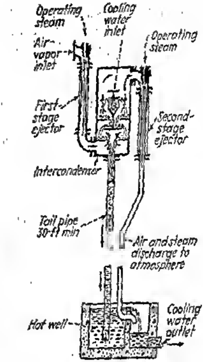

FIG. 8.—Two-stage Ejector with Direct-contact Barometric Intercondenser.

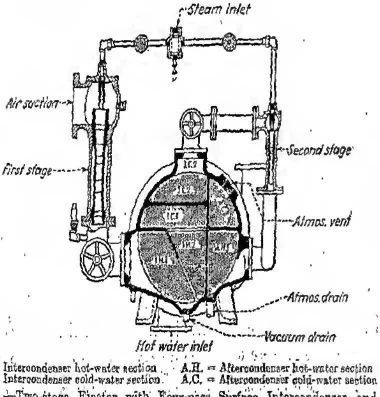

I.H. = Intercondenser hot-water section A.H. = Aftercondenser hot-water section
I.C. = Intercondenser cold-water section A.C. = Aftercondenser cold-water section

FIG. 9.—Two-stage Ejector with Four-pass Surface Intercondenser and Two-pass Aftercondenser.

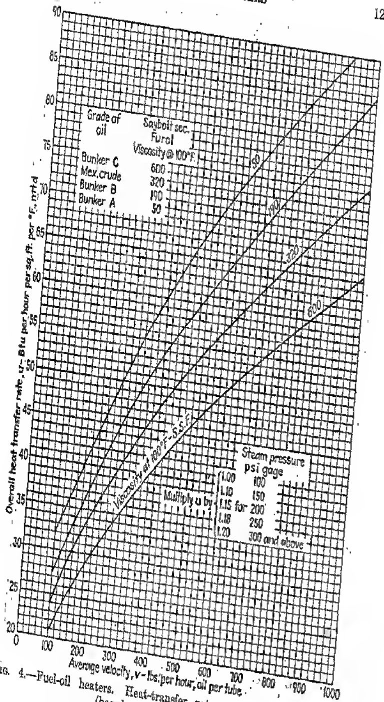

Fig. 4.—Fuel-oil heaters. Heat-transfer rates with ⅝-in. O.D. tubes (based on clean tube surface).

provided to recirculate condensate back to the condenser shell. Three-stage ejectors require two intercondensers and one aftercondenser.

Condensate from the intercondenser is usually returned to the condenser shell through a loop seal. Intercondenser steam space operates at high vacuum, 22 to 26 in., requiring a 10 to 15 ft water-leg seal.

The aftercondenser operates at atmospheric pressure. Drain can be piped to an open feed-water heater or trapped to the hot well.

Single-stage ejectors are customarily used up to 26.5 in. vacuum. For better vacuums up to 29.5, the two-stage ejectors should be used. Single-stage ejectors use about 7½ lb of live steam per lb of compressed vapor mixture at 26.5 in. vacuum. Two-stage non-condensing ejectors use 18 to 21 lb for 29 in. vacuum and 9 to 12 lb for 28 in.; the use of intercondensers reduces these quantities to 4 and 3 lb, respectively. The preceding figures apply to an average air-vapor mixture containing about 2.3 lb of steam per lb of air.

An augmenter is a device for boosting vacuum and is applied to a condenser served by a mechanical vacuum pump (Fig. 10). It consists of an ejector which may use exhaust steam of 3 to 10 lb gage pressure and an auxiliary condenser. With 5 lb operating pressure, it has been possible to augment the vacuum from 26 to 28.5 in. using 2 lb of exhaust steam per lb of air-vapor mixture compressed.

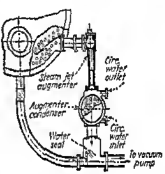

Fig. 10.—Vacuum Augmenter.

Power Required by Auxiliaries. The power required by large turbine auxiliaries varies from 1 to 3 percent, generally between 1 and 2 percent of the power of the main unit. In small installations, the power consumed varies from 2 to 10 percent. Centrifugal hot-well pumps or surface condensers generally require 0.05 to 0.10 hp for each 1,000 lb steam condensed per hour. Reciprocating air pumps require 0.10 to 0.3 hp per 1,000 lb steam per hour. Centrifugal air pumps require 0.25 to 0.5 hp per 1,000 lb steam per hour. The power required by circulating pumps varies with the design of the condensers, quantity of water pumped, and the efficiency of the pump. The pumping head may be as low as 10 ft in some condensers and as high as 35 ft or more in others, the average being about 20 ft. Pump efficiencies range from 75 to 85 percent for this service.

The steam required for auxiliaries, using moderate steam pressure, in pounds per brake horsepower per hour is as follows:

Circulating pumps, slow-speed, engine-driven	25 to 75
Circulating pumps, high-speed, engine-driven	40 to 100
Circulating pumps, turbine-driven, geared	25 to 30
Circulating pumps, turbine-driven, direct-connected	30 to 60
Air pumps, reciprocating	40 to 100
Hydraulic air pumps	40 to 55
Hot-well pumps, reciprocating	50 to 100
Hot-well pumps, centrifugal	40 to 60

The power required by jet condensers varies from 1 hp per 1,000 lb steam used per hour by the main turbine engine in the case of large units, to 3 hp per 1,000 lb steam for small units. Barometric condensers require 0.5 to 1.5 hp per 1,000 lb steam per hour.

just the opposite from type 2 as regards heat transfer, but the small passages tend to clog. There is a modification of type 1 gaining in favor owing to its low cost. Instead of being only slightly bent, the tubes have been made

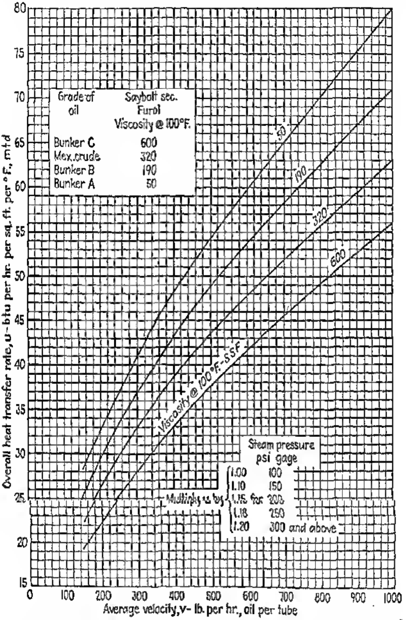

FIG. 5.—Fuel-oil heaters. Heat-transfer rates with ¾-in. O.D. tubes (based on clean tube surface).

into a coil. This minimizes expansion trouble, but the resistance to oil flow is increased. The design of type 1 only will be discussed here.

Because of the fact that the viscosity of the oil decreases so much owing to the rise in temperature, the pressure drop falls rapidly. Therefore it is

Most Economical Vacuum. No definite rule can be laid down for the most economical vacuum to be used. Each case must be considered separately on account of such factors as the cost of condensers, auxiliaries, and piping (all of which vary with temperature of inlet water), foundations, space, cost of coal, load factor, and fixed charges on main unit. For medium-size turbines a vacuum of 28½ in. and for large size 29 in. is generally considered the most economical with inlet water at 60 to 65 F. For engines, a vacuum of 26 in. is the most economical with water of ordinary temperatures. A higher vacuum will not increase engine economy.

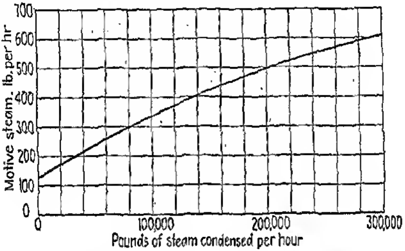

FIG. 11.—Steam Consumption of Two-stage Air Ejectors.

Salt-water Leakage. Where salt water must be used for circulating water in surface condensers, it is important that there should not be an excessive leakage into the condensed steam which is to be used for boiler feed. Glandless tubes with one floating tube sheet have been used successfully. If the hot-well water contains more than 1 percent of salt, it should not be supplied to the boilers. The method of determining this percentage is as follows:

Ten cc of the condenser water are measured out by a pipette, placed in a beaker, and two or three drops of potassium chromate solution added. A standard solution of silver nitrate is then added drop by drop from a burette, but only until the liquid in the beaker maintains a faint pink color on agitating. The volume of silver nitrate solution used is then recorded. Ten cc of the sample of circulating sea water are now measured out, 90 cc distilled water added, mixed, and 10 cc of the mixture taken. A few drops of the chromate solution are now added, and the silver nitrate added as before, the amount of the latter used being recorded. The amount of silver nitrate used for the circulating water multiplied by 10 and divided into the amount used for the condenser water and the quotient multiplied by 100 gives the percentage of sea-water leakage in the condenser water. The silver nitrate solution usually used is made up by dissolving 9.6 g silver nitrate in 2 liters of water. This is of such strength that 1 cc is equivalent to 1 mg of chlorine. Electrical-resistance recording indicators for salt-water leakage are available.

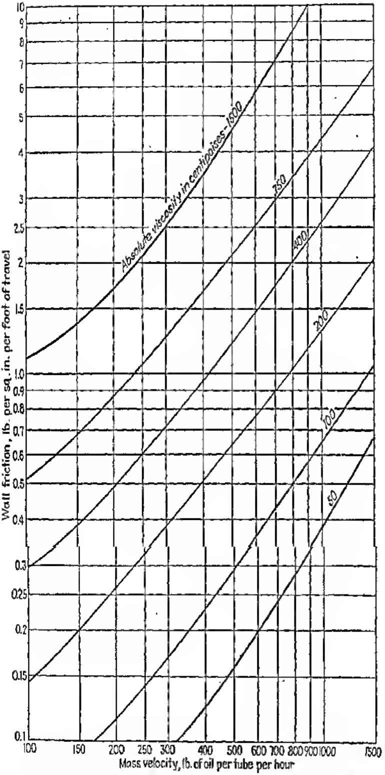

FIG. 6.—Fuel-oil friction with ⅝-in. O.D. tubing, No. 18 B.W.G.

HIGH-PRESSURE HEAT EXCHANGERS

BY

J. M. LABBERTON

General. Heat exchangers that operate at pressures higher than atmospheric present problems different from those operating at lower than atmospheric pressures, such as condensers. These high-pressure devices are used for transferring heat from steam to water, as in feed-water heaters; from water to water, as in drain coolers; from steam to oil, as in fuel-oil heaters; from oil to water, as in lubricating oil coolers.

Drain Coolers. The amount of surface required for drain coolers can be determined by using Eqs. (4), (5), (5a), and (6b), pp. 389, 391 to 393. These are generally shell and tube or double pipe devices in which there is a definite *velocity of water above the critical, i.e., turbulent flow. An example of the* use of this information follows.

Example. *Assume that it is desired to design a drain cooler to cool 3,400 lb per hr water at 186 to 110 F using 30,000 lb per hr water which enters at 102 F.*

Use 5/8 in. O.D., No. 18 B.W.G. tubing, Admiralty metal.

$$\text{I.D.} = 0.625 - 2(0.049) = 0.527$$

$$\frac{0.7854(0.527)^2}{144} = 0.001525 \text{ sq ft per tube}$$

Make velocity 5 fps.

$$0.001525 \times 5 = 0.007625 \text{ cu ft per tube per sec}$$

Average temperature of water $= \dfrac{186 + 110}{2} = 148$ F. 0.01633 cu ft per lb at this temperature.

$$\frac{0.007625 \times 3{,}600}{0.01633} = 1{,}680 \text{ lb per hr per tube}$$

Arrange so that water flow outside of tube is at approximately the same velocity as on the inside, i.e., 5 fps.

$$h_i = 160(1 + 0.012t_f)\frac{V_f^{0.8}}{D_f^{0.2}} \qquad (6b)$$

$t = 140$ F approximately. This is to be checked later.

$$h_i = 160(1 + 1.68)\frac{5^{0.8}}{0.527^{0.2}} = 430\frac{3.624}{0.8748} = 1{,}770$$

$$A_m = \frac{A_1 - A_0}{\log_e \dfrac{A_1}{A_0}} \qquad (4)$$

$$A_m = \frac{\dfrac{\pi 0.625}{12} - \dfrac{\pi 0.527}{12}}{\log_e \dfrac{0.625}{0.527}} = 0.153 \text{ sq ft per ft length}$$

$$\frac{3{,}400 \text{ lb per hr } (186 - 110)}{30{,}000 \text{ lb per hr}} = 8.6 \text{ F } \textit{rise in cold water}$$

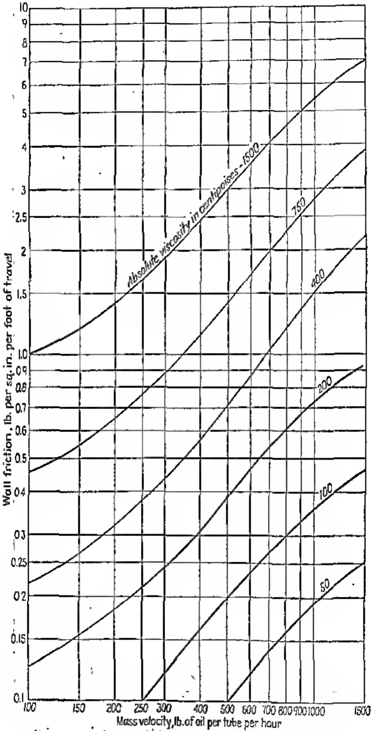

FIG. 7.—Fuel-oil friction with ¾-in. O.D. tubing, No. 16 B.W.G.

draw a circle cutting SA in B. Then draw a circle through A and B and touching one of the given circles (see preceding construction). This circle will touch the other given circle also. (Four solutions.)

To Draw an Annulus Which Shall Contain a Given Number of Equal Contiguous Circles (Fig. 44). (An annulus is a ring-shaped area enclosed between two concentric circles.) Let $R + r$ and $R - r$ be the inner and outer radii of the annulus, r being the radius of each of the n circles. Then the required relation between these quantities is given by $r = R \sin (180^\circ/n)$, or $r = (R + r)[\sin (180^\circ/n)]/[1 + \sin (180^\circ/n)]$.

FIG. 55.

Circle. Area $= \pi r^2 = \frac{1}{2}Cr = \frac{1}{4}Cd = \frac{1}{4}\pi d^2 = 0.785398d^2$ (table, p. 30). Here r = radius, d = diam., C = circumference $= 2\pi r = \pi d$ (table, p. 28).

Annulus (Fig. 54). Area $= \pi(R^2 - r^2) = \pi(D^2 - d^2)/4 = 2\pi R'b$, where R' = mean radius $= \frac{1}{2}(R+r)$, and $b = R - r$.

Sector (Fig. 55). Area $= \frac{1}{2}rs = \pi r^2(A/360°) = \frac{1}{2}r^2$ rad A, where rad A = radian measure of angle A, and s = length of arc $= r$ rad A (table, p. 44).

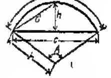

FIG. 56.

Segment (Fig. 56). Area $= \frac{1}{2}r^2$ (rad $A - \sin A$) $= \frac{1}{2}[r(s-c)+ch]$, where rad A = radian measure of angle A (table, pp. 34–35, 44). For small arcs, $s = \frac{1}{3}(8c' - c)$, where c' = chord of half the arc. (Huygens's approximation.) NOTE. $c = 2\sqrt{h(d-h)}$; $c' = \sqrt{dh}$ or $d = c'^2/h$, where d = diameter of circle; $h = r(1 - \cos\frac{1}{2}A)$, $s = 2r$ rad $\frac{1}{2}A$.

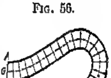

FIG. 57.

Ribbon bounded by two parallel curves (Fig. 57). If a straight line AB moves so that it is always perpendicular to the path traced by its middle point G, then the area of the ribbon or strip thus generated is equal to the length of AB times the length of the path traced by G. (It is assumed that the radius of curvature of G's path is never less than $\frac{1}{2}AB$, so that successive positions of the generating line will not intersect.)

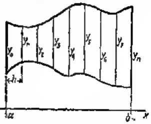

FIG. 58.

Simpson's Rule (Fig. 58). Divide the given area into n panels (where n is some even number) by means of $n+1$ parallel lines, called ordinates, drawn at constant distance h apart; and denote the lengths of these ordinates by $y_0, y_1, y_2, \ldots, y_n$. (Note that y_0 or y_n may be zero.) Then Area $= \frac{1}{3}h[(y_0 + y_n) + 4(y_1 + y_3 + y_5 \ldots) + 2(y_2 + y_4 + y_6 \ldots)]$, approx. The greater the number of divisions, the more accurate the result. Note: Taking $y = f(x)$, where x varies from $x = a$ to $x = b$, and $h = (b-a)/n$, then the

$$\text{error} = -\frac{1}{180}\frac{(b-a)^5}{n^4}f''''(X),$$

where $f''''(X)$ is the value of the fourth derivative of $f(x)$ for some (unknown) value $x = X$, between a and b.

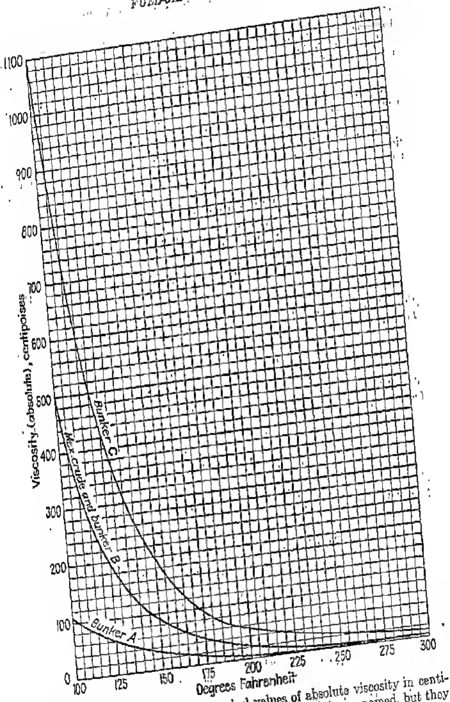

FIG. 8.—Fuel-oil viscosity. Typical values of absolute viscosity in centipoises. The values are not exact for all oils in the category named, but they are sufficiently accurate for practical determination of pressure drop in piping or heaters.

The combined flashed and generated vapors in the second-effect shell pass through the baffles and separator as in the first effect. The drains from the second-effect evaporator tube nest pass into the second-effect coil drain flash

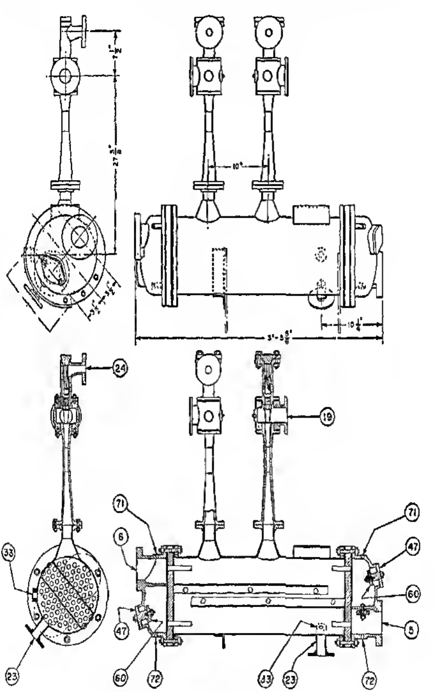

FIG. 14.—Air ejectors and after condenser for double-effect system. (*Courtesy of Foster Wheeler Corporation.*)

tank and finally join the drains from the distiller condenser. The vapor released in the second-effect coil drain flash tank, together with the vapor from the shell of the second-effect evaporator, passes into the distiller con-

good practice to have twice as many tubes per pass in the first half of the total passes as in the last half.

The curves in Figs. 4 to 8 will be used to determine the design of the fuel-oil heater. Their use is demonstrated by means of the following problem.

Example. It is desired to design a fuel-oil heater to heat 3,000 lb per hr of Bunker C oil from 100 to 230 F by means of 50 psi gage saturated steam and draining with no subcooling or at 298 F.

The specific heat of fuel oil of this character may be taken to be 0.48 over the practical temperature range with very little introduction of error. The amount of heat required is

$$(3{,}000)(230 - 100)(0.48) = 187{,}000 \text{ Btu/hr}$$

$$\frac{187{,}000 \text{ Btu/hr}}{911.6 \text{ Btu/lb}} = 205 \text{ lb/hr steam}$$

$$A_m = \frac{A_i - A_o}{\log_e \dfrac{A_i}{A_o}} = \frac{198 - 68}{\log_e \dfrac{198}{68}} = 122 \text{ F} \qquad (4)$$

Use $\frac{5}{8}$-in. O.D. tubing. Take velocity as 400 lb per tube per hr, average. $U = 41$ (see Fig. 4).

$$\text{Area} = \frac{187{,}000}{41 \times 122} = 37.4 \text{ sq ft}$$

Take eight passes. Two-thirds of surface in first four passes; one-third of surface in last four passes.

$$\tfrac{2}{3} \times 37.4 = 25 \text{ sq ft}$$

$$\frac{\text{Sq ft area}}{\text{Ft length}} = 0.1636 \text{ for } \tfrac{5}{8}\text{-in. O.D. tube}$$

If 400 lb per hr is average velocity $\frac{2}{3} \times 400 = 267$ lb per hr in first four passes. $\frac{4}{3} \times 400 = 534$ lb per hr in last four passes.

$$\text{Tube length} = l = \frac{\text{area}}{\text{number tubes} \times \dfrac{\text{area}}{\text{ft tube}}}$$

$$v = \frac{\text{lb oil}}{\text{tubes/hr}} = \frac{\text{lb oil/hr} \times \text{passes}}{\text{total tubes}}$$

$$267 = \frac{3{,}000 \times 4}{\text{total tubes}}$$

$$\text{Total tubes} = \frac{3{,}000 \times 4}{267} = 45 \text{ in first 4 passes}$$

There must be 48 to make an integral number of tubes per pass, or 6 tubes per pass. This necessitates a velocity correction. $v = \dfrac{3{,}000 \times 4}{48} = 250$ for first four passes, and 500 for last four passes.

$$U = 32 \text{ for } v = 250$$
$$U = 46 \text{ for } v = 500$$
$$U = \frac{32 + 46}{2} = 39 \text{ average}$$

denser. The distillate joins the drains from the second-effect evaporator tube nest, and both are pumped through the tubes of the distillate cooler into the test tank by the distillate condensate pump. The air ejector removes

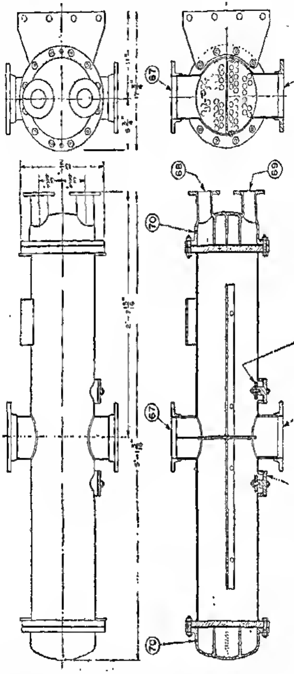

FIG. 15.—Distillate cooler for double-effect system. (*Courtesy of Foster Wheeler Corporation.*)

the noncondensible gases from the distilling condenser. The drains from the ejector after condenser join the drains from the first-effect evaporator tube nest and are returned to the ship's feed system.

$$\text{Area} = \frac{187{,}000}{39 \times 122} = 39.3$$

$$\tfrac{2}{3} \times 39.3 = 26.2 \text{ sq ft}$$

$$l = \frac{39.3}{(48 + 24)(0.1636)} = 3.33 \text{ ft}$$

Call it 3 ft 4 in.

For convenience, divide into four groups. Each pass could be worked out if desirable.

	Sq Ft
1st 2 passes 2 × 12 tubes × 0.1636 × 3.33 ft	13.1
2d 2 passes 2 × 12 tubes × 0.1636 × 3.33 ft	13.1
3d 2 passes 2 × 6 tubes × 0.1636 × 3.33 ft	6.6
4th 2 passes 2 × 6 tubes × 0.1636 × 3.33 ft	6.6
Total	39.4

If t_i = temperature of oil in and t_o = temperature of oil out, then the following expression may be used for determination of the temperature of the oil after having passed a given area:

$$t_o = t_i + t_e(1 - e^n)$$

where $n = -\dfrac{AU}{(\text{lb oil/hr})(0.48)}$

A = surface area
U = heat-transfer coefficient
t_e = temperature difference of steam and entering oil

To continue with the problem in hand. First two passes:

$$n = -\frac{(13.1)(32)}{(3{,}000)(0.48)} = -0.291$$

$$t_o = 100° + 198°(1 - e^{(-0.291)}) = 150 \text{ F}$$

Second two passes:

$$n = -0.291 \text{ (same as first two passes)}$$
$$t_o = 150 + 148(1 - e^{(-0.291)}) = 187 \text{ F}$$

Third two passes:

$$n = -\frac{(6.6)(46)}{(3{,}000)(0.48)} = -0.21$$

$$t_o = 187 + 111(1 - e^{(-0.21)}) = 208 \text{ F}$$

Fourth two passes:

$$n = -0.21$$
$$t_o = 208 + 90(1 - e^{(-0.21)}) = 225 \text{ F}$$

The latter value should be 230 F, *which is an indication of the error to be expected in this method of calculation.*

In any event, the average temperature of the oil in the first two passes is approximately 125 F. In the curve (Fig. 8) it can be seen that the absolute viscosity in centipoises is 420. In the curve (Fig. 6) it is seen that for a value of v = 250 (the velocity in the first pass) the wall friction is approximately 0.65 psi per ft travel. Pressure drop through the first two passes is therefore 0.65 ×6.66 ft = 4.35 psi

In similar manner, through the second two passes the average temperature is $\dfrac{150 + 187}{2}$ = 169 F.

Absolute viscosity = 110 centipoises
Wall friction = 0.16

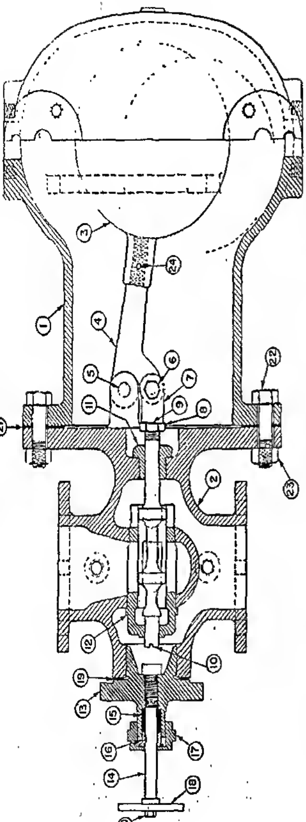

FIG. 16.—Drain regulator for double-effect system. (*Courtesy of Foster Wheeler Corporation.*)

Pressure drop through the second two passes is therefore $0.16 \times 6.66 = 1.07$ psi.

In similar manner, through the third two passes the average temperature is $\frac{187 + 208}{2} = 198$ F.

$$\text{Absolute viscosity} = 58 \text{ centipoises}$$
$$\text{Wall friction} = 0.17, \quad \text{for} \quad z = 500$$

Pressure drop through the third two passes is therefore

$$0.17 \times 6.66 = 1.15 \text{ psi}$$

In similar manner, through the fourth pass the average temperature is

$$\frac{208 + 225}{2} = 217 \text{ F}$$

$$\text{Absolute viscosity} = 40 \text{ centipoises}$$
$$\text{Wall friction} = 0.14$$

Pressure drop through fourth two passes is therefore

$$0.14 \times 6.66 = 0.94 \text{ psi}$$
$$\text{Total pressure drop is } 4.35 + 1.07 + 1.15 + 0.94 = 7.5 \text{ psi}$$

Drop through end boxes is negligible.

Oil Coolers. The amount of surface for oil coolers can be determined by calculating the water side as outlined on p. 1226 and by calculating the oil side by means of Fig. 3 on p. 394. μ in centipoises can be determined from Fig. 8 but when used in connection with Fig. 3 on p. 394 it must be multiplied by 2.42. The specific heat of oil, C_p, can be taken as 0.48.

$$K = 0.065 \text{ Btu/(hr)(sq ft)(deg F)(ft)}$$

The over-all heat transfer, U, can be determined as demonstrated on p. 392.

Evaporators. The purpose of evaporators is either to make fresh water from sea water or to evaporate the fresh water available on a ship and feed it into the feed system as vapor thus retaining almost all the heat that has been put into it. Small ships which do not use much fresh water usually are equipped with "single-effect" evaporators. Such systems evaporate the sea water in one shell, and the vapor therefrom is either used directly in the feed system or condensed and stored. Large ships and naval vessels which require a large amount of fresh water are equipped with "double-effect" or "triple-effect" evaporators. In such systems, the vapor from the first evaporator is led into a second evaporator and the heat therefrom used to evaporate still more water. If the vapor from the second evaporator is used to vaporize water in a third evaporator then it is said to be "triple-effect." It should be noted that the water is *not* double- nor triple-distilled.

Figure 9 shows a "single-effect" evaporator such as would be used on a small ship. This evaporator will produce 52,800 lb fresh water from sea water in 24 hr. Evaporation takes place at 10 psi gage, and the motive steam pressure may vary from 100 to 220 psi gage.

Feed water from the main condenser circulating water discharge is generally used for making fresh water. It enters the shell through the feed controller located on the side of the shell. The level of the water is maintained constant by this device. Approximately one-third of the water is

FEED SYSTEMS

BY

J. M. LABBERTON

General. The path traveled by the steam (or water) in any steam power plant is from boiler to turbine (or engine), thence to the condenser, and back to the boiler. This simple circuit requires a pump to force the water from the condenser to the boiler because of the higher pressure in the boiler. This is shown in Fig. 1.

That part of the circuit which handles water and which is necessary to feed this water to the boiler so that the boiler will have sufficient—no more nor less—material from which to make the required amount of steam is known as the feed system.

It is obvious that the only conditions under which the layout shown in Fig. 1 will operate successfully are absolutely unvarying load and no leakage.

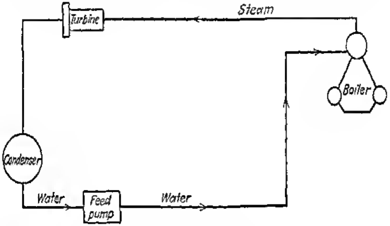

Fig. 1.—Basic feed system.

If the load is decreased, the feed pump will scavenge all the water out of the condenser and put too much in the boiler, filling it completely so that there will be no space for steam and, there being no elastic or compressible gas, the noncompressible water will burst the boiler or will flow into the turbine and destroy the blades.

If the load is increased, the condenser will fill with water and the boiler will run dry and then explode when water does reach it.

The effect of leakage is obvious.

Therefore, the scheme, as it stands, is impracticable, but it has two great advantages. All the heat in the condenser water is saved and available. The system is completely closed, and there is no possibility of the boiler feed water becoming contaminated with oxygen which would cause boiler-tube corrosion, assuming that there is no leakage of air into the system at the condenser, the pressure of which is below that of atmosphere. We can, however, render this system feasible by complicating it slightly with additional apparatus. Figure 2 shows the layout with the necessary items added.

These consist of a condensate pump, a surge or feed tank, a boiler-water-level regulating valve, and a means for adding water that may be lost by

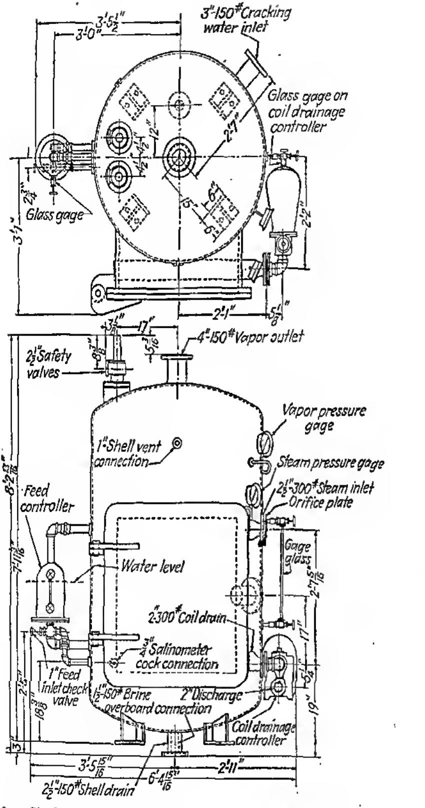

FIG. 9a.—Single-effect evaporator—elevation and plan. (*Courtesy of Foster Wheeler Corporation.*)

leakage. This latter water to be added is known as make-up feed. The boiler water level is controlled here by the regulator, and the variations of the water in the circuit are compensated for changes in the amount of water in the surge tank.

It will also be noticed that a separate circuit for steam to drive auxiliaries is included. These auxiliaries, of course, include the turbines for driving the condensate and main feed pumps, or the auxiliaries may consist of a turboelectric generator which furnishes power for the motors that drive the pumps.

In the case of the scheme shown in Fig. 1 it could be supposed that the feed pump was driven by an extension on the main turbine shaft.

The scheme shown in Fig. 2 is practicable. In fact, many ships are on the high seas, as you read this, operating with just such a feed system. It will be noted that the make-up water is shown being fed into the condenser. This is done so that the air ejectors, included among the auxiliaries, may have a chance to remove some of the air brought in by the raw feed water. Another

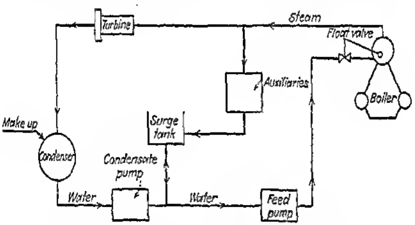

Fig. 2.—Practical open-feed system.

reason is that no pump or pressure above atmospheric is required to inject make-up feed into the system, the lower pressure of the condenser permitting atmospheric pressure to force the water in. Often, however, the make-up feed is put into the open surge tank.

This open surge tank places this system in the class of "open" feed systems. It is the weak spot in this system because oxygen in the air will surely dissolve in this water, and this corrosive solution will be carried into the boiler.

Deaeration. Attempts to obviate this trouble have resulted in the evolution of various types of "closed" feed systems. Obviously, since changes in load must be experienced, a surge tank or its equivalent should be incorporated in the system. No air should enter this surge tank directly from the atmosphere. Since in various sections of the feed system pressures range from condenser pressure to slightly above full boiler pressure, we have quite a choice of pressures at which to operate the surge tank. If it is placed in any part of the system at atmospheric pressure or below, it must be closed to atmosphere. However, it must also be vented at the top otherwise any air that might get into it, through leakage or in any other manner, would soon become bound at the top and eventually reduce the capacity of the tank as well as dissolve in the water and nullify the effects sought.

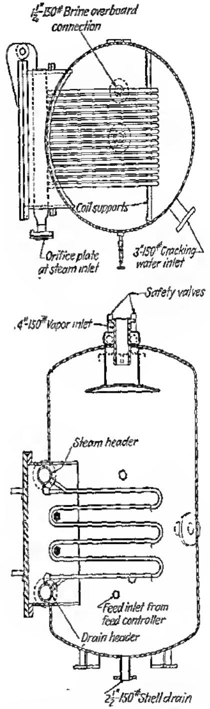

FIG. 9b.—Single-effect evaporator—horizontal section and sectional elevation. (*Courtesy of Foster Wheeler Corporation.*)

The only way to vent such a tank would be into a portion of the system at lower pressure. Naturally, the choice settles on the condenser, and this is often done. Figure 3 shows a popular general type of closed feed system incorporating a surge tank operating at lower than atmospheric pressure and vented to the condenser. Naturally, better elimination of air would be accomplished if the water in the surge tank were boiling. Since the pressure in the tank is low, boiling will take place at low temperatures and the heat can be supplied by means of low-pressure steam. In the case of Fig. 3, this steam is part of the exhaust of auxiliary turbines which are designed to operate at rather high exhaust pressure, say 10 psi gage. All the heat in this exhaust steam is not lost but passes on to the boiler in the feed water.

There is one portion of it, however, which is lost and that is one of the bad features of this system. Since the water in the surge tank is caused to boil, water vapor as well as air passes over to the condenser. The water vapor is

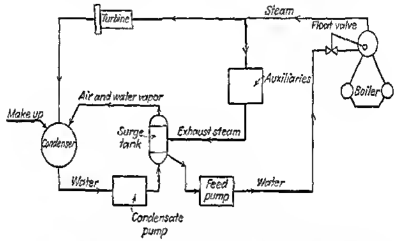

FIG. 3.—Closed-feed system with deaerating surge tank below atmospheric pressure.

condensed, and the air passes out through the air ejectors. However, in the condensation of the water vapor, all the latent heat of vaporization, approximately 1000 Btu per lb, goes out into the sea with the condenser circulating water and is lost forever. The object in the boiling is to get rid of the air and entrain it with vapor passing over. The more the vapor, the better the air elimination but, by the same token, the greater the loss.

Another undesirable feature is that the resistance to air and vapor flow between surge tank and condenser should be kept low. This means a very large pipe (or conduit) or an extremely short run or both. Often this is inconvenient.

If the surge tank is placed in any part of the feed system at higher than atmospheric pressure, the tank can be vented to atmosphere or to any pressure lower. The choice of venting points is practically limited to the atmosphere or to the condenser. If to the condenser, there is no point in going to a pressure higher than atmosphere for the surge tank. If to the atmosphere, there is no point in going to any pressure except one slightly higher than atmospheric.

converted into vapor which passes up through the baffled vapor outlet into the condenser. The remaining water is discharged overboard as concentrated brine.

Descaling, otherwise known as "temperature cracking," should be performed every 24 hr. This consists in shutting off the steam and filling the shell with cold sea water. Then steam is suddenly admitted, and the rapid resultant expansion causes any scale to crack and fall off.

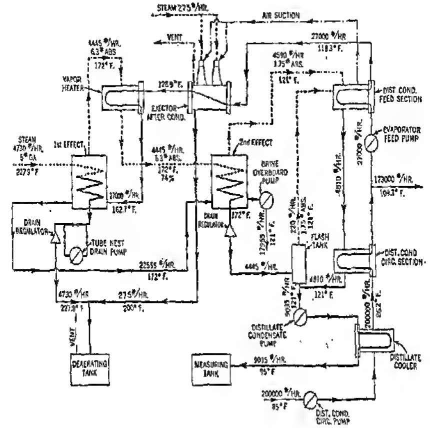

FIG. 10.—Double-effect evaporator. Heat-flow diagram under clean-tube conditions—26,000 gal per 24 hr. (Courtesy of Foster Wheeler Corporation.)

Access to the coils is gained by means of the door shown.

Figures 10 to 16 show the elements and flow cycle of a double-effect evaporator capable of 167,000 lb fresh water in 24 hr.

Feed water from the sea chest is pumped into the shell of the distillate cooler by the distilling condenser circulating pump. It then passes through the tubes of the distilling condenser condensing section where it absorbs heat from the vapor in the shell. After passing through the condensing section, about 85 percent of the feed water is pumped overboard. The remainder is picked up by the evaporator feed-pump suction and is further heated by being fed to the distiller condenser feed section, the air ejector after condenser, the first-effect vapor heater, in that order, and finally entering the shell of the first-effect evaporator. Part of the feed water will flash when it flows from the first-effect evaporator shell into the second-effect evaporator shell because of the low pressures. Brine, from the second-effect evaporator shell, is pumped overboard by the brine overboard discharge

A pressure slightly higher than atmospheric is the one usually chosen when venting to the atmosphere (see Fig. 4).

For the reasons mentioned before, it is well to have the atmospheric surge tank boiling. However, if water vapor boils off, not only is the heat lost as in the case of the surge tank venting to the condenser, but the valuable water is lost and the engine room is filled with opaque fog and vapor which is both annoying and dangerous.

The problem then resolves itself into getting rid of the air yet retaining the vapor. This is done by having this mixture of air and water vapor go through what is called a "vent condenser." This is a nest of cooling tubes, the surface temperature of which is considerably lower than 212 F. This cooling is usually accomplished by running the feed water, which is on its way to the deaerating surge tank, first through the coils of this vent condenser. Naturally, the water vapor will be condensed and fall back into the surge tank while the air, which is noncondensable under such circumstances, will

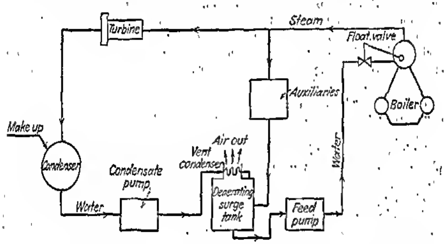

FIG. 4.—Closed-feed system with deaerating surge tank above atmospheric pressure.

pass on out. Usually, since it is not quite possible to obtain a perfect balance to the point where all the water vapor is condensed and all the air passes out of its own volition, a duct or conduit is led from the vent condenser to some point outside the machinery space and connected with the ventilation exhaust or some similar system. Of course, the air is not dry, so the feed system does lose a small amount of water in this manner.

It should be borne in mind that all of the latent heat of vaporization of the water boiled off with the air in the surge tank is saved aside from that small amount of water vapor leaving the vent condenser with the air. This heat is transferred to the feed water entering the surge tank. Consequently, considering the vent condenser as an integral part of the surge tank assembly, there is a mere circulation of heat within this assembly and none is lost. This conception greatly simplifies calculation of the heat balance of the complete system.

Pumps. Reference to Fig. 1 will disclose that only one pump is necessary. The suction of this pump will be at lower than condenser pressure whereas the discharge is somewhat greater than boiler drum pressure; however, reference to Fig. 2 will disclose two pumps in the feed line. The necessity

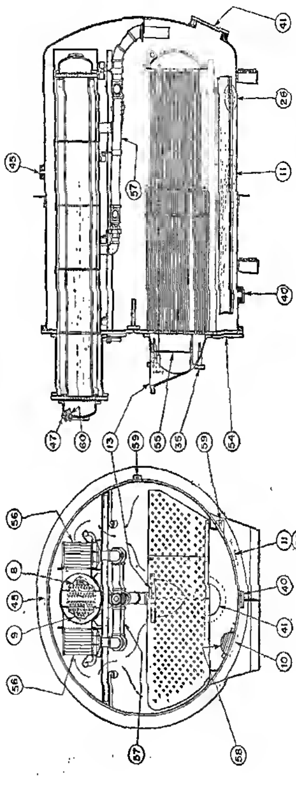

FIG. 11.—First-effect evaporator of double-effect system. (*Courtesy of Foster Wheeler Corporation.*)

for the additional or "condensate pump" is clear when it is realized that the open surge tank has atmospheric pressure on it and that this pressure would force all of the water back into the condenser. A similar condition exists in the case of Fig. 3 where the surge tank, though not at atmospheric pressure, is still at higher than condenser pressure. The same is true of Fig. 4.

In other words, in cases where turbine exhaust is at lower than atmospheric pressure, at least two pumps are necessary in the feed line in any practical feed system. Sometimes an additional or "booster" pump is desirable as will be discussed later.

In general, there should be at least one condensate pump for each condenser except sometimes in the case of auxiliary turbogenerator condensers. Since it must have a suction pressure approaching vacuum, it is invariably operated under submerged conditions and must be placed underneath the condenser it serves. On board ship this is sometimes difficult to do because the bottom of the condenser should also be placed low, it being under the main propulsion turbines, so as to keep the center of gravity of the total machinery weight low for stability reasons. In general, also, condensate pumps are driven by an electric motor of simple and rugged construction such as that of a squirrel-cage induction motor if a-c power is available on the ship, otherwise by a d-c shunt motor. The discharge pressure may be anywhere from 20 to 75 psi gage.

The feed booster pumps, when used, take water at a suction pressure about equal to that of condensate pump discharge. They discharge at from 50 to 100 psi gage.

Main feed pumps take water at a suction pressure of anywhere from atmospheric to 75 psi gage and discharge at somewhat higher than boiler-drum pressure.

This may be a proper place to mention that, if the suction pressure of the main feed pump is anywhere near the boiling point, corresponding to temperature and pressure of the water entering, boiling or vaporization is likely to occur and the pump will "cavitate" or vapor-lock. A margin of pressure should be assured here. To state this in another way, if the feed-water temperature entering the pump is high enough and its pressure is suddenly reduced, it will flash into steam. This steam has the same pressure, of course, and occupies the same space that water would have occupied. Its density, however, is relatively low and, when it finds its way into the passages at the entrance of the pump impeller, the centrifugal force, which is the basis of the discharge pressure, decreases greatly and the pump operates erratically if at all.

The principal purpose of a feed booster pump is to ensure a sufficiently high suction pressure on the main feed pump. For this reason, surge tanks at atmospheric pressure, whether deaerating or not, are usually placed at as high a point as practicable to ensure pressure at the main feed-pump intake.

Sometimes the main feed pump takes water from the last feed heater, if there are several stages of feed-water heating, and discharges directly into the boiler. Under such circumstances the feed water would be quite hot, considerably above 212 F and, in that event, a booster feed pump is almost essential so that no point will be at a pressure so low as to permit vaporization or steam formation in the feed line.

The actual specification as to capacity and power required to drive will be taken up in more detail on p. 1282.

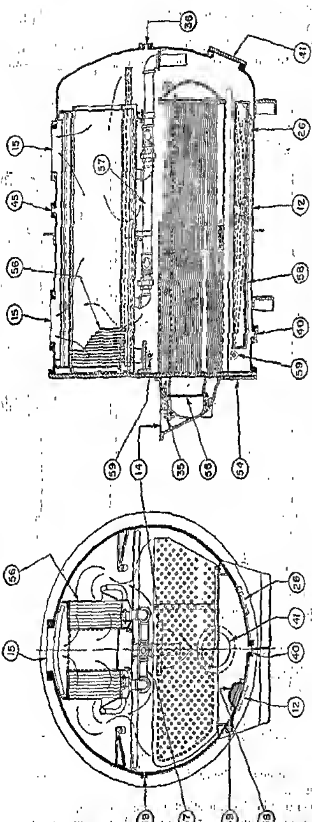

FIG. 12.—Second-effect evaporator of double-effect system. (Courtesy of Foster Wheeler Corporation.)

Heating. The main condenser in marine work is generally designed for operation at 1.5 in. Hg abs pressure. This pressure is somewhat higher than is common in the best stationary or land plants, but it should be remembered that space and weight on board ship are at a great premium. Consequently the design is a compromise with all the factors having influence on the design according to their importance, as is the case in all good engineering.

In the case of land installations, the condensers can be so built that there is very little subcooling of the condensate below the temperature corresponding to condenser pressure and, consequently, less heat is required for feed-water heating.

In the case of marine condensers, cramped space results in an unavoidable amount of subcooling. A reasonable figure to use as a basis for calculation and to specify is 5 F.

The saturation temperature corresponding to 1.5 in. Hg abs is 92 F; 5 F below this is 87 F; therefore it may be assumed that the lowest temperature of the feed water is 87 F and that the feed water must be raised to the final feed-water temperature from this value of 87 F. The value to be specified for final temperature will be discussed shortly.

Naturally, all savings possible should be made concerning heat in the system. Any heat lost or thrown away must be supplied by fuel.

There are many drains around a ship which are hotter than 87 F. These come from air-ejector condensers, gland leak-off condensers, condensate from lower stage feed heaters, etc. The temperature of this mixture, which can be collected in a drain tank, might be from 175 to 200 F. If a collecting tank is used, it should be vented either to atmosphere or to one of the condensers, otherwise it will soon become airbound and drains will not flow in.

These drains, which, of course, consist of good clean, distilled water, can then be led to the condenser but should be taken via a heat exchanger generally referred to a "drain cooler." On one side of the surface would be the cool feed water from the condenser entering at about 87 F and on the other side would be the relatively hot drains entering at about 175 to 200 F. This passage through the drain cooler might raise the feed water 5 to 20 F in temperature.

However, it might be desirable to pass the feed water through the air-ejector condensers first.

Air ejectors in marine service are assembled close to the condenser shell and are usually in two stages. The first-stage condenser will absorb all of the heat of the ejector motive steam plus about two-thirds of the heat of the water vapor carried over from the main condenser less the heat of the drains leaving. The second-stage condenser will absorb all of the heat of the ejector motive steam plus the other third of the heat of the water vapor carried over from the main condenser (and continued to be carried over to the second stage) less the heat of the drains leaving.

At full power, not more than 5 or 6 F will be picked up by the feed water in passing through the intercooler or aftercooler, nor more than 10 or 12 F in passing through the combination. Consequently feed water at 110 F could still well utilize the heat available in a drain cooler.

In general, passing the feed water through the air-ejector system first is to be preferred. It is conducive to better air-ejector action when the intercoolers and aftercoolers are colder.

Up to the present time, the discussion has been on the basis of one main propulsion turbine exhausting to one condenser. In the case of a *four-screw*

pump in sufficient quantity to maintain a maximum of 1½ thirty-seconds concentration.

The steam passes through a reducing valve, reducing the pressure to 5 psi gage or less, to the first-effect evaporator tube nest. The drains from the

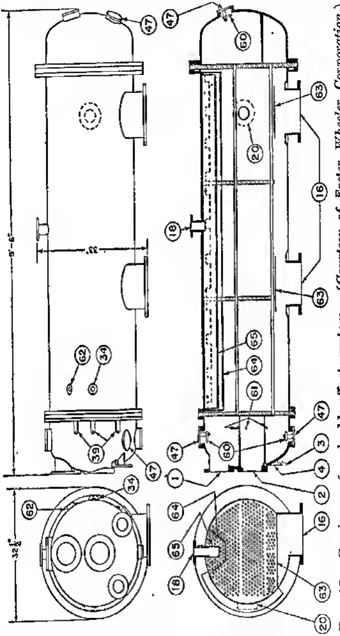

FIG. 13.—Condenser for double-effect system. (*Courtesy of Foster Wheeler Corporation.*)

tube nest are returned to the feed system of the ship by the first-effect tube nest drain pump.

Vapor, generated in the first-effect evaporator shell, rises through a system of baffle plates and a separator to the vapor heater tubes in the upper half of the shell. This vapor then passes into the second-effect evaporator tube nest.

ship there would be four sets of turbines, condensers, and air ejectors. They should then be considered as groups, each group acting as a unit of one turbine, and so on.

However, there will also be on the ship electric turbogenerators. These will operate in groups or, at times, there may be only one turbogenerator operating, with the main propulsion secured or shut down as when in port. In that event the turbogenerators are a little system within themselves and should be so considered. Therefore, it is common practice to run the condensate from the turbogenerators or, as some of the older marine people call them, the "dynamo condensers" through its own air-ejector system and then join it with the main or feed at a point just beyond the main aftercooler.

Often a connection is made between the exhaust of the turbogenerators and the main condensers. Then, when at sea and the main condensers are in operation, the turbogenerator condensers can be secured together with condensate pumps and air ejectors, and the turbogenerator turbine exhaust fed into the main condensers. This is an economical scheme but should be considered carefully before being adopted because of complication, weight, and space of piping.

From this point on to the boilers, there are two basic methods of applying heat to the feed water. One is to use exhaust steam from the auxiliaries plus the heat from such high-pressure drains as the steam heating system, fuel-oil heating system, etc. The other is to use steam bled from the main turbines plus the heat from the high-pressure drains. In the latter case, the auxiliaries would be driven by electric power, and the electric generator turbines would exhaust to condensers. Consequently there would be no auxiliary exhaust steam available for feed heating.

The former method will be considered first. It has already been mentioned and discussed to some extent. It is hardly practical to use more than one exhaust pressure on board ship because, if several exhaust pressures are used, there must be several exhaust-steam lines. Too much complication in the attempt to gain economy in marine steam installations is not justified and, since reliability and simplicity go hand in hand to some extent, some economy must be sacrificed to obtain a reasonable degree of simplicity and low cost.

Therefore, assuming that there will be but one exhaust pressure, the value of this pressure can be determined when the value of the feed-water temperature at the entrance to the boiler (or economizer) has been chosen. The saturation temperature of the exhaust steam used for feed-water heating should be approximately 25 F greater than that of the feed-water final temperature.

If a deaerating surge tank at slightly more than condenser pressure is used, such as shown in Fig. 3, the saturation or boiling temperature in this tank will be quite low, very close to 100 F. Consequently, if this is the only place where heat is applied to the feed water, a very low feed-water temperature will be the result or practically no feed-water heating at all. This is uneconomical and unsatisfactory because little or no use could be made of the exhaust steam from the auxiliary turbines. Therefore, under such circumstances, it would be better to put a feed heater of the shell and tube or surface type just ahead of the main feed pump or just after it.

If it is placed just ahead of the main feed pump, it will probably be necessary to install a feed booster pump between the surge tank and the feed heater so as to ensure high enough suction pressure at the main feed pump to avoid vaporization or cavitation at this point, as mentioned before.

Ellipse (Fig. 59; see also p. 140). Area of ellipse $= \pi ab$. Area of shaded segment $= xy + ab \sin^{-1}(x/a)$. Length of perimeter of ellipse $= \pi(a + b)K$, where $K = [1 + \frac{1}{4}m^2 + \frac{1}{64}m^4 + \frac{1}{256}m^6 + \ldots]$, $m = (a - b)/(a + b)$.

If it is placed just after toe main feed pump, the feed heater is at full boiler-drum pressure, slightly higher, in fact; this, though practicable, is obviously undesirable. Many ships, however, are in operation with feed heaters so placed.

With this system there is a wide choice of feed temperatures available, as high as 250 or 300 F with an exhaust pressure of possibly 75 psi gage. This, however, is unusual and the feed temperature is generally chosen at approximately 215 or 220 F with an exhaust pressure of 10 psi gage, approximately.

If a feed system incorporating an atmospheric deaerating surge tank is chosen, the feed temperature, in the case of single-stage heating such as is now being discussed, is fairly definitely fixed.

Water boils at 212 F at atmospheric pressure. Therefore the actual temperature in the tank must be higher owing to the higher pressure in the tank. Under no circumstances should it be less than 213 F, for then no deaerating effect would exist.

As mentioned before, as the main feed pump would take suction from this tank and discharge to the boilers, the tank should be placed as high as possible.

It should be borne in mind that, in the case of feed-heating systems using exhaust steam from auxiliaries for feed heating, once the feed temperature is decided upon, this fixes the exhaust pressure of the auxiliaries. This means that just enough exhaust steam, through very narrow limits, should be available for this feed heating and no more. If there is too little steam, the feed temperature will not be brought up to the proper point—considering deaeration, among other things. If there is too much exhaust steam, there will be a wasteful boiling off of water in the case of a deaerating surge tank and, in the case of a shell and tube feed heater, the exhaust steam will simply not condense and there will be a rise in exhaust pressure which will adversely affect auxiliary turbine performance.

Therefore, the heat balance must be carefully worked out to ensure just enough turbine-driven auxiliaries, the others being electrically driven, to furnish the proper amount of steam.

If conditions of variable power rates exist caused by running at various speeds under different circumstances, such as are encountered in the case of naval vessels, the problem is considerably complicated. Under such circumstances, the only practical solution, from an economical viewpoint, is to select auxiliaries so that there will be just enough steam under the most adverse condition and then feed the excess back into the main propulsion turbines at one of the lower stages under the other conditions.

This is bad from a turbine standpoint for the reason that at various loads on the turbines, various pressures occur at a given stage, and there would therefore have to be several feedback points on the turbine for a given exhaust pressure. Another argument against it is that the largest, most expensive, most difficult to design from a mechanical stress standpoint, part of the turbine is the low-pressure end. And, with this steam injected at low pressures, this undesirable situation is amplified.

The other basic method of heating feed water, i.e., by the use of steam bled from the turbines plus the heat from the high-pressure drains, is the more economical method and should be used whenever practically possible.

The fundamental nature of this economy can be readily understood when it is realized that the largest loss in the power plant is due to the heat given up in the exhaust. This exhaust is at approximately 110 F, and all the latent

involved. Saturated steam at higher temperatures is less deleterious than superheated steam. With the latter, the valve seats deteriorate rapidly.

HEAT BALANCE

Suppose that it is desired to design or specify the propulsion machinery for a ship having a displacement of 17,600 tons and requiring 8,500 shp; 100 kw electrical power is required for purposes other than auxiliary equipment for propulsion; and 2,000 lb per hr desuperheated steam is required for evaporators and reciprocating pumps. The electrical power for purposes other than propulsion is usually specified by the naval architect, whereas the steam consumption for the evaporators and small pumps is calculated by the marine engineer.

Assuming that 800 F total temperature of steam is satisfactory, reference to the Mollier diagram (Fig. 2) will disclose that, without reheat, the optimum pressure to use is not far from 600 psia; *i.e.*, with an exhaust pressure of 1.5 in. Hg abs.

It may appear that this temperature and pressure are arrived at rather quickly and without much investigation, but actually there is not much argument to it. Certainly the highest temperature should be used commensurate with the heat-withstanding qualities of the materials available. This is obvious from the Mollier diagram. Also, the proper pressure is obvious from the diagram aside from the argument for a higher pressure to reduce pipe size and taking into account moisture in the exhaust steam which must be a limited amount (see p. 1266).

Taking into account the pressure and temperature drop from boiler-superheater outlet to turbine throttle, the boiler-superheater-outlet condition should be approximately 615 psia at 810 F. The drop through the superheater of the boiler should be approximately 25 psi; therefore, the drum pressure should be 640 psia.

Some desuperheated steam will be necessary. If the drop through the desuperheater is considered negligible and 50 F of superheat remains (an average condition), the condition of the steam at the desuperheater outlet would be 615 psia, 539 F with an enthalpy of 1245.4 Btu per lb.

Using the method outlined on p. 1193, a condition curve of steam through the turbine is obtained (see Fig. 2).

Propulsion Steam Turbine Consumption. The combined efficiency with gears of an 8,500-shp unit should be approximately 76 percent (see Fig. 14, p. 1195). Therefore the water rate (W.R.) should be

$$\text{W.R.} = \frac{2{,}545}{(\text{isentropic drop})e_{\text{turbine}}}$$

The isentropic drop from 600 psia, 800 F, to 1.5 in. Hg is 509.7 Btu per lb, therefore,

$$\text{W.R.} = \frac{2{,}545}{(509.7)(0.76)} = 6.58 \text{ lb/shp-hr}$$

$$\text{Total steam} = 8{,}500 \times 6.58 = 56{,}000 \text{ lb/hr, no bleeding}$$

Turbogenerator Steam Consumption. Turbogenerators should be installed with sufficient capacity to obtain approximately 80 percent of full load when the ship is operating at full power. The reason for this is to

heat of vaporization of the steam being condensed in the condenser is thrown away in warming up sea water.

As was discussed in the case of using exhaust from the auxiliary turbines, practically all of the heat in the steam fed to auxiliary turbines is recovered in heating feed water. Instead of sea water carrying it away, feed water carries it to the boiler.

By bleeding steam from the main propulsion turbines, an attempt is made to recover part of the heat fed in, which is ordinarily lost in exhaust (see Fig. 5).

Obviously, if steam is bled from the turbines at a given pressure, the maximum temperature to which feed water can be heated is the saturation temperature corresponding to that pressure. Also, assuming for the sake of simplicity, a shell and tube type of heater with bled steam condensing in the shell, the maximum amount of steam that will flow out of the turbine and be

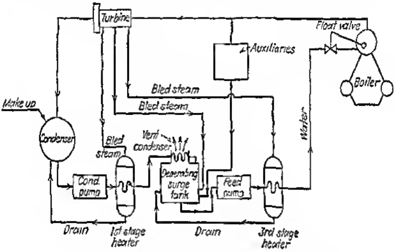

Fig. 5.—Regenerative feed-water heating system.

condensed is that amount sufficient to heat the feed water to the saturation temperature.

Naturally, the greatest economy will occur when the maximum amount of steam is diverted from the heat-wasting condenser and, as seen above, this amount is limited.

Assume that a certain amount of steam has been condensed in the condenser and assume that, at a pressure point only slightly higher than condenser pressure, steam is bled and used for heating this condensate from the condenser up to a temperature corresponding to the bled pressure. Assume further that the condensed steam that was bled is mixed with the water from the condenser, all now at the same temperature.

This bled steam has been completely useful. Its available energy has been applied to the turbine, and a certain percentage of mechanical energy, depending upon the efficiency of the turbine and gearing, has been transmitted to the propeller. The remaining heat has been utilized for a purpose for which otherwise fuel would have had to be supplied. True, the heat involved has been small because it was possible to raise the temperature of the feed water only slightly, but the gain was definite and positive.

permit the adding of more electrical load (after the ship has been in service) in the way of ventilating motors, etc., without the necessity of starting up another generator.

Assume, as a basis for preliminary calculation, that 175 kw will be necessary for auxiliary equipment for propulsion. This will be verified later.

$175 + 100 = 275$ kw operating load. Install two 350-kw d-c generators. One to operate at 275 kw. The combined efficiency of a 350-kw turbogenerator should be approximately 53.5 percent (see Fig. 25, p. 1204). Therefore the water rate should be

$$\text{W.R.} = \frac{3{,}413}{(\text{isentropic drop})e_{\text{turbogenerator}}}$$

Using the same throttle-steam conditions and exhaust pressure as in the case of the main turbines, the isentropic drop would be 509.7 Btu per lb. Therefore,

$$\text{W.R.} = \frac{3{,}413}{(509.7)(0.535)} = 12.55 \text{ lb/kwhr}$$

at full load. Taking the efficiency at 80 percent load to be 95 percent as good, the fractional-load water rate should be $12.55/0.95 = 13.2$ lb/kwhr. The total steam consumption should, therefore, be

$$275 \text{ kw} \times 13.2 \text{ lb/kwhr} = 3{,}630 \text{ lb/hr}$$

Air-ejector Steam Consumption. Refer to curve, Fig. 11, p. 1225. In the case of regenerative feed-water heating with three stages, approximately 90 percent of the throttle steam, no bleeding, goes to the condenser. Therefore, the steam to the main condenser would be approximately

$0.90 \times 56{,}000 = 50{,}400$ lb per hr (To be checked later)
240 lb per hr steam to main ejectors
140 lb per hr steam to turbogenerator ejectors

Feed-water Temperature. As demonstrated on p. 1252, the temperature of the feed water in the deaerating feed heater corresponds to the pressure in that heater. It is not necessary that the pressure be greater than sufficient to drive the air out. Probably 10 psi gage or 25 psia is a fair value to use in calculations. This would correspond to a temperature of 240 F, the temperature of the feed water leaving the deaerating heater.

Since the turbine exhaust temperature is 92 F (corresponding to 1.5 in. Hg with no subcooling) and since the saturation temperature at 600 psia is 486 F, $486 - 92 = 394$ F is the maximum possible rise in feed water through the three heaters. Referring again to p. 1263, it is seen that the optimum rise should be approximately

$$40 + 8 \times 3 = 64\% \text{ of the maximum rise}$$

or

$$0.64 \times 394 \text{ F} = 252 \text{ F, actual rise}$$
$$252 + 92 = 344 \text{ F}$$

call it 345 F for the final feed-water temperature. This corresponds to 126 psia. To care for some temperature and pressure drop the steam should be bled from the turbine at approximately 20 psi higher pressure or 145 psia.

Now, suppose that more steam is bled at a point slightly higher and the process repeated. A further small saving would result. Suppose this process to be repeated and repeated at small increments of pressure until the maximum bleeding pressure possible is reached. This maximum pressure is the throttle pressure of the turbine.

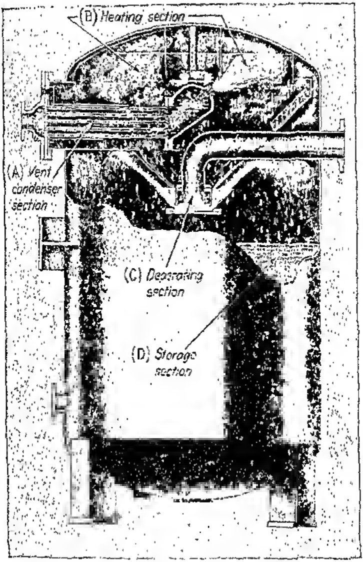

FIG. 6.—Deaerating feed-water heater and vent condenser. (*Courtesy of Elliott Company.*)

If an infinite number of bleeding pressures and heaters is used, each one to bring the feed-water temperature up to the saturation temperature at that point, the maximum economy will be realized.

This can be readily seen to be true when viewed from the standpoint that under such conditions the maximum amount of steam is permitted to pass through the turbine and only the latent heat of vaporization of the bled steam is required for feed heating, yet all the steam that it is possible to use for this purpose has been used.

If there is 5 F subcooling in the main condenser, this being a fair figure to use, the actual temperature of the condensate leaving the condenser should be approximately $92 - 5 = 87$ F.

In going from the condenser to the deaerating feed heater at 240 F there is a temperature rise of $240 - 87 = 153$ F. Assume that half of this is accomplished in the first-stage heater, then

$$153/2 + 87 = 163.5 \text{ F or } 164 \text{ F}$$

should be the temperature of the feed water leaving the first-stage heater. As this corresponds to 5.25 psia, the bleeding pressure should be made 10 psia to care for the drops. The bleed pressures at the turbine as well as the feed-water temperatures and enthalpies leaving the various heaters are shown on the accompanying table. It is assumed that loss of enthalpy in going from the turbine to the heater in each case is negligible.

Stage	Feed temp, deg F	Enthalpy Btu per lb	Bleed pressure, psia
1st	164	132	10
2d	240	208	35
3d	345	316	145

The major part of the condensate going through the first-stage heater is made up of main turbine and turbogenerator steam (see Fig. 1). Therefore, using an estimate of the amount of steam to be bled for first-stage, heating can be obtained.

50,400 lb/hr, main turbines
3,630 lb/hr, turbogenerators
54,030 lb/hr

Enthalpy of condensate leaving the two condensers at 87 F is 55 Btu per lb.

$$54{,}030 \text{ lb/hr } (132 - 55) = 4{,}160{,}000 \text{ Btu/hr to be supplied.}$$

As previously mentioned, the air ejectors should use 380 lb per hr and, if the single-stage gland leak-off ejector takes 70 lb per hr, which is a reasonable figure, the total air-ejector steam would be $380 + 70 = 450$ lb per hr. Each pound of this steam is good for approximately 1000 Btu per lb. The total is, therefore, good for $450 \times 1000 = 450{,}000$ Btu per hr.

$$4{,}160{,}000 - 450{,}000 = 3{,}710{,}000 \text{ Btu/hr}$$

Referring to the condition curve of the turbine (Fig. 2), it is seen that the enthalpy of the steam bled for the first-stage heater at 10 psia is 1123 Btu per lb. Assume that the drain leaves at an enthalpy corresponding to 5 psia or 130 Btu per lb, then the heat transferred will be $1123 - 130 = 993$ Btu per lb.

$$\frac{3{,}710{,}000 \text{ Btu/hr}}{993 \text{ Btu/lb}} = 3{,}740 \text{ lb/hr}$$

to be bled for the first-stage heater.

FIG. 7.

All feed water goes through the deaerating feed heater, and the additional feed from the various auxiliaries averages up approximately to an enthalpy corresponding to the temperature of the feed leaving the heater; consequently, in raising from 164 to 240 F there is required

$$(54{,}030 \text{ lb/hr})(208 - 132) = 4{,}110{,}000 \text{ Btu/hr}$$

Referring to the condition curve of the turbine (Fig. 2), it is seen that the enthalpy of the steam bled for the deaerating feed heater at 35 psia is 1195 Btu per lb. This steam leaves as feed water at 208 Btu per lb. Therefore there is a transfer of 1195 − 208 = 987 Btu per lb.

$$\frac{4{,}110{,}000 \text{ Btu/hr}}{987 \text{ Btu/lb}} = 4{,}170 \text{ lb hr}$$

to be bled for the deaerating heater or second stage.

Ordinarily, in this class of ship, the steam for all purposes is approximately 30 or 40 percent more than the main turbine steam to condenser. Assume it is 40 percent.

$$1.4 \times 50{,}400 = 70{,}500 \text{ lb/hr}$$

This leaves the deaerating heater at 208 Btu per lb and is raised to 316 Btu per lb in the third-stage heater. Referring to the condition curve of the turbine (Fig. 2), it is seen that the enthalpy of the steam bled for the third-stage heater at 145 psia is 1295 Btu per lb. Assume that the drain leaves at an enthalpy corresponding to 130 psia or 319 Btu per lb. Then the heat transferred will be 1295 − 319 = 976 Btu/lb.

$$\frac{(70{,}500 \text{ lb/hr})(316 - 208)}{976 \text{ Btu/lb}} = 7{,}780 \text{ lb/hr}$$

to be bled for the third-stage heater.

With these estimated values of bled steam, turbine throttle steam can be calculated.

Extraction or Bleeding. Figure 3 shows the "condition curve" of a turbine on a Mollier diagram. The point a is the throttle condition, and the path abc is the isentropic path, or the path followed under conditions of 100 percent internal efficiency of the turbine. Actually, the path will be $ab'c''$. The available energy is, of course, $h_a - h_c$. But if steam is extracted or bled from the turbine at the pressure indicated by the pressure curve bb', then the available energy remaining in this bled steam would be $h_{b'} - h_{c'}$, and this is lost in so far as turbine work output is concerned.

If $w_{b'}$ = weight of steam bled at b', w_t = weight of throttle steam required to perform the remaining work, $w_{b'}$ would have done if it had not been bled. Then

$$w_{b'}(h_{b'} - h_{c'}) = w_t(h_a - h_c)$$

This is on the basis that the internal efficiency of the complete turbine is equal to the internal efficiency of that section from b' to c''. This, of course, is not strictly true, owing to the reheat differing (see p. 1192), but it is sufficiently close for all practical purposes. The extra work and calculation in

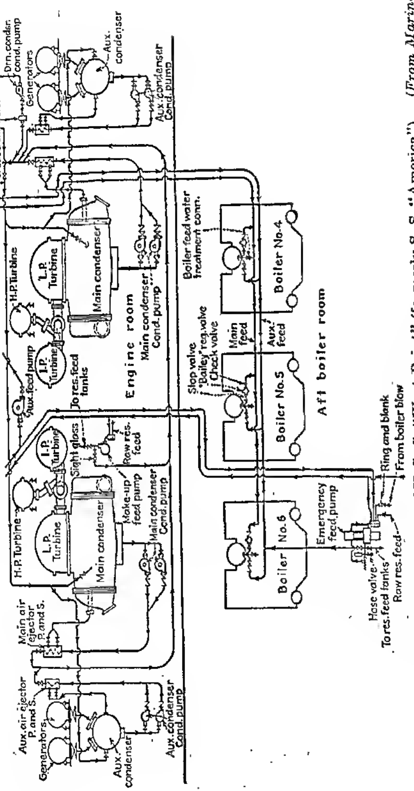

FIG. 7.—Feed and condensate system of U. S. S. "West Point" (formerly S. S. "America"). (*From Marine Engineering and Shipping Review.*)

correction for this small difference are not justified. Therefore,

$$\frac{h_{b'} - h_{c'}}{h_a - h_c} w_{b'} = w_t$$

or the steam to be added at the throttle, when $w_{b'}$ is bled, in order to maintain the same power output.

Induction or Feeding Back. If, on the other hand, there is excess steam of lower than throttle pressure that must be disposed of and the condition of this steam is as indicated by b' and if

$w_{b'}$ = weight of steam feed into turbine under condition b'

w_t = weight of throttle steam required to perform the work that $w_{b'}$ amount of steam would perform

then $$w_{b'}(h_{b'} - h_{c'}) = w_t(h_a - h_c)$$

therefore, $$\frac{h_{b'} - h_{c'}}{h_a - h_c} w_{b'} = w_t$$

or the steam saved at the throttle when maintaining the same power output

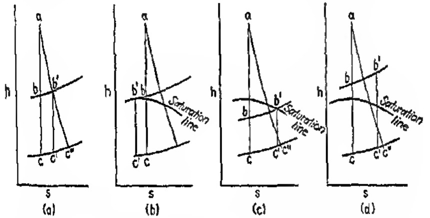

FIG. 3.—Extraction (bleeding) and induction (feeding back) of steam from and into turbines.

In either extraction or induction the term $(h_{b'} - h_{c'})/(h_a - h_c)$ is known as the **replacement factor.**

It should be carefully noted that when steam is bled from a turbine it may come out superheated, saturated, or wet, depending on the stage from which it is bled. However, when steam is inducted, it is usually saturated and may be superheated but should never be wet. In any event, it is highly improbable that the inducted steam will be of exactly the same character as that in the stage being entered. In Fig. 3*b*, *c*, and *d*, note the various circumstances that may exist in inducting or feeding back at a given pressure. Note that the condition in a stage may be superior or inferior to the condition of the steam coming in, but that, in any event, the isentropic drop from b', properly located, must be used as demonstrated above.

Steam to the Main Condenser. Referring to the condition curve (Fig. 2), the replacement factor for the first bleed point or that for the first-

To obtain a better conception, the two extremes and a medium point of bleeding will be considered.

Suppose that steam is bled from the turbine at throttle pressure and at this point only. This steam is used to heat feed water to the temperature corresponding to this pressure. At this point, the bled steam contains considerable available energy which could be converted to mechanical energy. This high-grade steam is used to do, to a large extent, a low-grade job, *i.e.*, to bring low-temperature feed water up to a high temperature when a low-pressure, low-grade steam could bring the temperature part of the way up just as well. This low-grade steam is what is left after the high-grade steam has been used to obtain some mechanical energy.

Obviously, this is not so economical as in the case of an infinite number of bleed points and heaters.

Suppose that steam is bled from the turbine at exhaust pressure. Of course, that is merely conventional operation and all the latent heat of vaporization of all the steam is lost in the condenser and that is not at all economical. It is what we are trying to avoid.

Suppose that steam is bled from the turbine at a point midway between throttle and exhaust. This is certainly better than bleeding at throttle pressure because some of the available energy of the bled steam has been converted to mechanical energy, and it is certainly better than no bleeding at all because some of the latent heat of vaporization has been salvaged. But it is not so economical as using an infinite number of heaters.

Therefore, it follows that the more the bleed points or stages of heating, the better the economy.

Naturally, it is impossible to install an infinite number of stages of heating on board ship. It would be impossible to have more stages of heating than there are pressure stages in the turbine and this is far too many for practical purposes. The maximum number that is, at present, acceptable to most ship operators is three, and it has been generally found that equal increments of feed-water temperature are best for economy. But this cannot always be exactly realized in marine installations because the construction of the turbines influence bleeding pressures and the middle-stage temperature is fixed by the deaerating surge tank.

The foregoing discussion has made no mention of losses, but there are, of course, losses. In the first place, since an infinite number of heaters is not used there is some loss due to using relatively high-temperature steam to bring relatively low-temperature water up to approximately the steam temperature. Also, there is a drop in pressure between the turbine and the heaters as well as a differential in temperature between steam and water in shell and tube heaters. In the second place, there is loss of heat due to heat transfer to the outside atmosphere from the various heaters and piping.

There are, on the other hand, various attendant advantages which are very important. (1) The turbine blading design becomes more rugged owing to the fact that the greater amount of steam passes through the upper, smaller, high-pressure stages. (2) The size and cost of the turbine exhaust shell become less for a given capacity. (3) The size and cost of the condenser decrease.

The best feed-water temperature has been the subject of considerable study. Obviously, the greater the number of heaters, the greater the optimum feed-water temperature. As already demonstrated, for an infinite number of heaters, the optimum temperature is the saturation temperature of the throttle steam, or the highest temperature it is possible to reach.

stage heater would be

$$\frac{h_{b'} - h_{e'}}{h_s - h_c} = \frac{1{,}123 - 965}{509.7} = 0.311$$

For the second bleed point or second-stage heater, the replacement factor would be

$$\frac{h_{b'} - h_{e'}}{h_s - h_c} = \frac{1{,}195 - 948}{509.7} = 0.485$$

For the third bleed point or third-stage heater, the replacement factor would be

$$\frac{h_{b'} - h_{e'}}{h_s - h_c} = \frac{1{,}295 - 926}{509.7} = 0.725$$

A table can now be made like the accompanying.

Heater	Bled steam, lb per hr	Replacement factor	Steam added, lb per hr
1st stage	3,740	0.311	1,162
2d stage	4,170	0.485	2,020
3d stage	7,780	0.725	5,650
Total bled	15,690	To be added	8,832

Throttle steam = 56,000 + 8832 = 64,832 lb/hr
To condenser = 64,832 − 15,690 = 49,142 lb/hr

(This is within 2 percent of the estimated condensate used to estimate amount of bleeding. This is close enough for the preliminary work now being done.)

A preliminary steam summary can now be made

PRELIMINARY STEAM SUMMARY

	Lb per hr	
Main propulsion turbines	64,832	
Turbogenerators	3,630	
Total superheated steam		68,462
Evaporators and reciprocating pumps	2,000	
Air ejectors	450	
Total desuperheated steam		2,450
Total steam, all purposes		70,912

This is sufficiently close to the 70,500 lb per hr used to estimate the bleeding of the turbine.

The heat balance will now be calculated. Refer to the steam flow diagram (Fig. 1) and start at the turbogenerator.

From the turbogenerator condenser, assume 10 lb per hr gland leak-off steam from all turbine bearings.

When operating at 8,500 shp, have all drains from the atmospheric drain tank enter the drain cooler.

Of course, the quantity or value really under consideration is the temperature rise because the bled steam really raises the temperature above that of condensate temperature. An empirical expression which may be used to obtain a first estimate of the optimum temperature is as follows:

Temperature rise of feed water in percent of maximum possible rise
$$= 40 + 8 \text{ (number of heaters)}$$

When the final temperature has been determined in this manner, it may be well to work out a couple of temperatures on either side to see if there is any change in economy. However, the efficiency curve at the optimum point is quite flat and there can be considerable change in temperature with very little change in economy.

The amount to be bled and the effect on turbine throttle steam value are also taken up on p. 1272.

It is not always practical to use this most economical scheme. Obviously, for certain bleeding pressures, it is set for a certain load on the turbines, normally the designed cruising speed of the ship. If the load on the turbines is changed to any extent, the pressures in the various stages will change and the corresponding temperatures of the bled steam to the various heaters will be entirely different. This will result in the system's being out of adjustment and a loss of economy.

It is not practical to have a multiplicity of bleeding points on a turbine and to change from one to the other quickly.

In the case of most naval vessels, maneuverability is important, and this involves wide changes in load. In such cases it may be best to have most auxiliary units steam-driven and have one bleed point on the turbine, this at auxiliary exhaust pressure; then steam can either be bled from or fed back in at this point when there is not enough or too much auxiliary exhaust for feed heating. In other words, economy must sometimes be sacrificed for flexibility.

In the case of destroyers, the cruising speed at which the ship operates more than 90 percent of the time requires power less than 10 percent of that required at full speed. In such case, it might be best to have a special cruising turbine and use bled steam for feed heating, driving the small cruising auxiliaries electrically; then for powers above this, steam-driven auxiliaries with their attendant flexibility could be used and their exhaust used for feed heating. In short, there would be two systems on one ship, one of less than 10 percent the capacity of the other.

"Carry-over," or water in the air removed by air ejectors, can generally be taken as 0.00002 *times the steam condensed. Also it can be assumed that* 70 percent of this carry-over is condensed in the intercooler and the other 30 percent in the aftercooler.

$$0.00002 \times 3{,}630 = 0.0726 \text{ lb/hr (negligible)}$$
$$\text{Turbogenerator intercooler drain} = 70 \text{ lb/hr}$$

Total condensate from turbogenerator condenser = 3,630 + 70 = 3,700 lb/hr. At 1.5 in. Hg,

$$\text{Temperature} = 92 - 5 = 87 \text{ F}$$
$$\text{Enthalpy} = 55 \text{ Btu/lb}$$

Total heat leaving turbogenerator condenser = 3,700 × 55 Btu/lb
= 203,500 Btu/hr

Gland Leak-off Condenser. Assume drains at 209 F or 177 Btu per lb, 10 lb per hr steam at atmospheric pressure.

10 lb/hr × 1150 Btu/lb	11,500 Btu/hr
10 lb/hr × 177 Btu/lb	1,770
Heat transferred	9,730 Btu/hr
Heat leaving turbogenerator	203,500
Total heat leaving condenser	213,230 Btu/hr

$$\frac{213{,}230 \text{ Btu/hr}}{3{,}700 \text{ lb/hr}} = 57.7 \text{ Btu/lb or } 90 \text{ F}$$

Turbogenerator Intercooler. The temperature of the leaving drains is approximately 121 F or at 89 Btu per lb.

70 lb/hr × 1245.4 Btu/lb	87,200 Btu/hr
70 lb/hr × 89 Btu/lb	6,230
Heat transferred	80,970 Btu/hr
In condensate	213,230
In condensate leaving	294,200 Btu/hr

Drain to turbogenerator condenser.

Turbogenerator Aftercooler. The temperature of the leaving drains is approximately 209 F or at 177 Btu per lb. There are two ejectors blowing into this condenser: the gland leak-off ejector, and the second stage of the turbogenerator ejection system, each at 70 lb per hr.

70 lb/hr × 1245.4 Btu/lb	87,200 Btu/hr
70 lb/hr × 1245.4 Btu/lb	87,200
Entering	174,400 Btu/hr
140 lb/hr × 177 Btu/lb	24,800
Transferred	149,600 Btu/hr
In condensate	294,200
In condensate leaving	443,800 Btu/hr

$$\frac{443{,}800 \text{ Btu/hr}}{3{,}700 \text{ lb/hr}} = 120 \text{ Btu/lb or } 152 \text{ F}$$

Drain to atmospheric drain tank.

Atmospheric Drain Tank. "Carry-over" from main condenser,

$$0.00002 \times 49{,}142 \text{ lb/hr} = 0.98 \text{ lb/hr}$$

HEAT BALANCE AND SIZES OF AUXILIARIES

BY

J. M. LABBERTON

STEAM PRESSURE AND SUPERHEAT

Steam pressure and steam temperature should be chosen to obtain the greatest amount of available energy from steam, the available energy being defined as that energy useful to the turbine or isentropic heat drop. Reference to the typical steam Mollier diagram (Fig. 2) will disclose that the available energy increases as the temperature increases, throttle pressure and exhaust pressure being held constant. However, there is a limit to the temperature due to the materials available for use in the upper stages of the turbine. At present this limit is practically about 1000 F, but much developmental work is being done, especially in view of the gas turbine (see p. 1205), and it is probable that the practical temperature will be raised considerably in the near future. The Mollier diagram, on the other hand, discloses that, although the available energy does increase as the pressure increases, this increase does not amount to much after 600 psia is passed, provided temperature and exhaust pressure are held constant. Consequently there is little to be gained by increasing the pressure above 600 psia if available energy is the only consideration.

Since steam volume decreases almost directly with pressure increase, temperature being held constant, there is some argument involving the size of high-pressure piping in favor of a pressure higher than 600 psia. The smaller this piping, temperature being held constant, the easier is the problem of pipe stresses. The maximum pressure without reheat should probably be 850 to 900 psia.

In the event that reheating of the steam, after it has passed through a portion of the turbine (see p. 1202), is contemplated, then the pressure should be increased to not less than 1,200 psia, otherwise the volumes of steam involved during reheating will be so large as to be impractical.

As to exhaust pressure, when space, weight, and economy are considered, 1.5 in. Hg abs seems to be the optimum pressure at the present time. This permits a condenser of good reasonable design.

FEED SYSTEM

As demonstrated on pp. 1258 to 1263, there is little argument in favor of any feed system other than the regenerative system, except in cases where a ship must be run continuously at several widely different speeds, as in the case of naval vessels.

A steam-flow diagram, such as that shown in Fig. 1, is a practical one and can be modified to include more or less stages of feed-water heating or to eliminate or add drain coolers, etc., as may be desirable from an economical or simplification standpoint. Calculations will show how much is to be saved at various points by the units under consideration.

It will be noted that the diagram includes a "contaminated" water system. This permits a small separate system to take care of water that might become contaminated with oil or other substances injurious to the boilers or other parts of the main system. As shown, this small system feeds the fuel-oil

Call it 1 lb per hr. Although this is divided 70 and 30 percent in the inter- and aftercoolers, in order to avoid dealing in fractions of a pound, assume that all of this carry-over is condensed in the intercooler. Therefore, the only drain from the main aftercooler is due to the motive steam of the air ejector.

Main aftercooler............	120 lb/hr × 177 Btu/lb = 21,240 Btu/hr
Turbogenerator aftercooler...	140 lb/hr × 177 Btu/lb = 24,780
Gland leak-off..............	10 lb/hr × 177 Btu/lb = 1,770
	270 lb/hr 47,790 Btu/hr

Drain Cooler. From first-stage feed-water heater at 5 psia (assuming pressure drop in coming from bleed point on turbine), 162 F or 130 Btu per lb.

3740 lb/hr × 130 Btu/lb = 486,000 Btu/hr
270 lb/hr × 177 Btu/lb = 47,790
4010 lb/hr 533,790 Btu/hr

$$\frac{533{,}790 \text{ Btu/hr}}{4{,}010 \text{ lb/hr}} = 133 \text{ Btu/lb or } 185 \text{ F entering.}$$

These drain coolers are usually designed with sufficient surface to result in a leaving drain temperature of 110 F or 78 Btu per lb.

$$133 - 78 = 65 \text{ Btu/lb heat transferred}$$
$$\text{Total transfer} = 4010 \text{ lb/hr} \times 65 \text{ Btu/lb} = 260{,}500 \text{ Btu/hr}$$

This transferred heat will be applied to the combined condensates of the turbogenerator condenser and main condenser. Calculations for the latter follow.

From Main Condenser.

	Lb per Hr
Main propulsion turbines..................................	49,142
Gland leak-off..	−10
Drain cooler..	4,010
Main intercooler..	121
Through air ejectors..	−1
Entering main condensate pump..............................	53,262

Assuming some subcooling as in the case of the turbogenerator condenser, the condensate is at 55 Btu per lb.

$$\text{Heat leaving} = 53{,}262 \text{ lb/hr} \times 55 \text{ Btu/lb} = 2{,}930{,}000 \text{ Btu/hr}$$

Main Intercoolers. 121 F drain leaving, 89 Btu per lb.

120 lb/hr × 1245.4 Btu/lb........................	149,600 Btu/hr
1 lb/hr × 1102 Btu/lb..........................	1,102
121 lb/hr..	150,702 Btu/hr
121 lb/hr × 89 Btu/lb...........................	10,780
Heat transferred..............................	139,922 Btu/hr
In condensate.................................	2,930,000
In condensate leaving..........................	3,069,922 Btu/hr

$$\frac{3{,}069{,}922 \text{ Btu/hr}}{53{,}262 \text{ lb/hr}} = 57.6 \text{ Btu/lb or } 90 \text{ F}$$

Drain to main condenser.

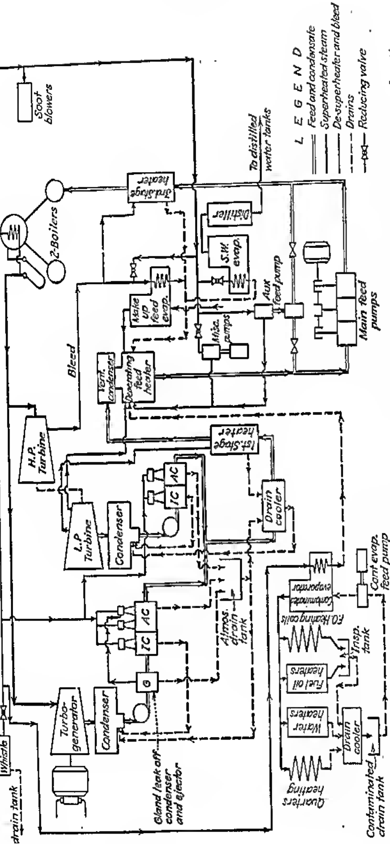

FIG. 1.—Steam and feed flow diagram. Closed regenerative system with three stages of feed-water heating.

Main Aftercooler. 209 F drain leaving, 177 Btu per lb.

120 lb/hr × 1245.4 Btu/lb	149,600 Btu/hr
120 lb/hr × 177 Btu/lb	21,240
Heat transferred	128,360 Btu/hr
In condensate	3,069,922
In condensate leaving	3,198,282 Btu/hr

$$\frac{3{,}198{,}282 \text{ Btu/hr}}{53{,}262 \text{ lb/hr}} = 60 \text{ Btu/lb or } 92 \text{ F}$$

Combination of Condensates.

53,262 lb/hr at	3,198,282 Btu/hr
3,700 lb/hr at	443,800
56,962 lb/hr at	3,642,082 Btu/hr

$$\frac{3{,}642{,}082 \text{ Btu/hr}}{56{,}962 \text{ lb/hr}} = 64 \text{ Btu/lb or } 96 \text{ F}$$

This enters the cold side of the drain cooler.

Drain Cooler.

In condensate	3,642,082 Btu/hr
Transferred in cooler	260,500
56,962 lb/hr at	3,902,582 Btu/hr

$$\frac{3{,}902{,}582 \text{ Btu/hr}}{56{,}962 \text{ lb/hr}} = 68.8 \text{ Btu/lb or } 101 \text{ F}$$

First-stage Heater.

Enthalpy of steam entering heater	1123 Btu/lb
Enthalpy of drain leaving	130
Transferred per lb	993 Btu/lb

3,740 lb/hr × 993 Btu/lb = 3,710,000 Btu/hr

In condensate	3,902,582
In condensate leaving	7,612,582 Btu/hr

$$\frac{7{,}612{,}582 \text{ Btu/hr}}{56{,}962 \text{ lb/hr}} = 134 \text{ Btu/lb or } 166 \text{ F}$$

164 F was the temperature sought for this stage.

Deaerating Feed Heater and Vent Condenser. A total of 4,170 lb per hr is to be bled from the main turbines at 1195 Btu per lb and introduced directly into the heater. A total of 7,780 lb per hr is to be bled at the highest pressure, 145 psia, and with an enthalpy of 1295 Btu per lb for use in the third-stage heater. Assume that 100 lb per hr of this is diverted to the make-up feed evaporator where it will be used to generate steam at approximately 20 psia which enters the deaerating feed heater for make-up. Such a scheme assures absolutely pure make-up water, and the heat used for vaporizing the feed water is not lost. The remaining 7,680 lb per hr will condense in the third-stage heater and return to the deaerating heater as water at 319 Btu per lb.

The fluid entering the deaerating heater will include the drain from the make-up feed evaporator or 100 lb per hr at 196 Btu per lb, assuming no subcooling.

heaters and quarters-heating system with low-pressure saturated steam. Such a system has the additional advantage over schemes that use steam, the

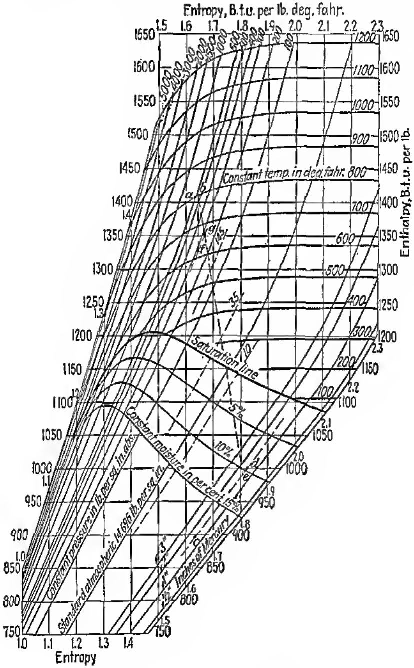

FIG. 2.—Condition curve of propulsion turbines.

pressure of which is reduced by means of reducing valves, in that there is no superheat. Superheat is bad in a quarters-heating system because of the corrosive action of superheated steam in spite of the low temperatures

The sum of the fluids entering the deaerating heater is as follows:

In condensate	56,962 lb/hr	7,612,582 Btu/hr
In bled steam	4,170 lb/hr × 1195 Btu/lb	4,980,000
Evaporators and reciprocating pumps	2,000 lb/hr × 335 Btu/lb	670,000
Make-up evaporator	100 lb/hr × 196 Btu/lb	19,600
Third-stage heater drain	7,680 lb/hr × 319 Btu/lb	2,450,000
	70,912 lb/hr	15,732,182 Btu/hr

$$\frac{15{,}732{,}182 \text{ Btu/hr}}{70{,}912 \text{ lb/hr}} = 222 \text{ Btu/lb or } 254 \text{ F}$$

This is too high a temperature at this point, and it is apparent that the bleeding from the turbine must be reduced. However, a good method is to accept this temperature for the time being and continue the calculations for the third-stage heater, then make all corrections at once.

It is well to note at this point that the total weight of feed water leaving the deaerating heater should be the same as the weight of steam, all purposes (see Preliminary Steam Summary, p. 1272), as no more water is added from this point on to the boiler. Note also that it is assumed here that the steam requiring make-up is lost from the system at the same pressure as that of the make-up steam entering the deaerating heater. This simplifies the calculations and is as justifiable an assumption as any other.

Third-stage Heater.

	Btu per Lb	Btu per Hr
Enthalpy of steam entering	1295	
Enthalpy of drain leaving	319	
Heat transferred per lb	976	
7,680 lb/hr × 976 Btu/lb		7,500,000
In condensate		15,732,182
Total in feed		23,232,182

$$\frac{23{,}232{,}182 \text{ Btu/hr}}{70{,}912 \text{ lb/hr}} = 328 \text{ Btu/lb or } 356 \text{ F}$$

This is 11 F too high or 12 Btu per lb too much.

The enthalpy leaving the second-stage heater should have been 208 Btu per lb whereas it was 222 Btu per lb or 14 Btu per lb too much. Therefore, the second stage should be decreased 14 Btu per lb and the third stage increased 2 Btu per lb.

$$\frac{70{,}912 \text{ lb/hr} \times 14 \text{ Btu/lb}}{(1195 - 208) \text{ Btu/lb}} = 1005 \text{ lb/hr reduction}$$

$4170 - 1005 = 3165$ lb/hr to be bled for second stage.

$$\frac{70{,}912 \text{ lb/hr} \times 2 \text{ Btu/lb}}{976 \text{ Btu/lb}} = 145 \text{ lb/hr increase}$$

$7780 + 145 = 7925$ lb/hr to be bled for third stage.

Corrected Steam Summary and Heat Balance. Make a table for the new bleedings similar to the one on p. 1272.

of inscribed circles; $s = \sqrt{(r - r')^2 + h^2}$; a,a' = sides of lower and upper bases; n = number of sides.

Frustum of Right Circular Cone (Fig. 73). Volume = $\frac{1}{3}\pi r^2 h[1 + (r'/r) + (r'/r)^2] = \frac{1}{3}\pi h(r^2 + rr' + r'^2) = \frac{1}{4}\pi h[(r + r')^2 + \frac{1}{3}(r - r')^2]$. Lateral area $= \pi s(r + r')$; $s = \sqrt{(r - r')^2 + h^2}$.

Any Pyramid or Cone. Volume $= \frac{1}{3}Bh$. B = area of base; h = perpendicular distance from vertex to plane in which base lies.

Any Pyramidal or Conical Frustum (Fig. 74). Volume $= \frac{1}{3}h(B + \sqrt{BB'} + B') = \frac{1}{3}hB[1 + (P'/P) + (P'/P)^2]$. Here B, B' = areas of lower and upper bases; P, P' = perimeters of lower and upper bases.

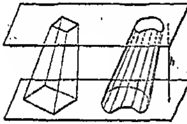

FIG. 74.

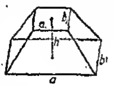

FIG. 75.

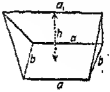

FIG. 76.

Obelisk (Frustum of a rectangular pyramid. Fig. 75).
Volume $= \frac{1}{6}h[(2a + a_1)b + (2a_1 + a)b_1] = \frac{1}{6}h[ab + (a + a_1)(b + b_1) + a_1b_1]$.

Wedge (Rectangular base; a_1 parallel to a,a and at distance h above base. Fig. 76). Volume $= \frac{1}{6}hb(2a + a_1)$.

Sphere. Volume $= V = \frac{4}{3}\pi r^3 = 4.188790r^3 = \frac{1}{6}\pi d^3 = 0.523599d^3$ (table, p. 36) = $\frac{2}{3}$ volume of circumscribed cylinder. Area $= A = 4\pi r^2$ = four great circles (table, p. 30) $= \pi d^2 = 3.14159d^2$ = lateral area of circumscribed cylinder. Here r = radius; $d = 2r$ = diameter $= \sqrt[3]{6V/\pi} = 1.24070\sqrt[3]{V} = \sqrt{A/\pi} = 0.56419\sqrt{A}$.

Hollow Sphere, or spherical shell. Volume $= \frac{4}{3}\pi(R^3 - r^3) = \frac{1}{6}\pi(D^3 - d^3) = 4\pi R_1^2 t + \frac{1}{3}\pi t^3$. Here R,r = outer and inner radii; D,d = outer and inner diameters; t = thickness $= R - r$; R_1 = mean radius $= \frac{1}{2}(R + r)$.

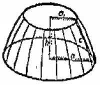

FIG. 77.

Spherical Segment of One Base. Zone (spherical "cap" of Fig. 78). Volume $= \frac{1}{6}\pi h(3a^2 + h^2) = \frac{1}{3}\pi h^2(3r - h)$ (table, p. 38). Lateral area (of zone) $= 2\pi rh = \pi(a^2 + h^2)$. Note: $a^2 = h(2r - h)$, where r = radius of sphere.

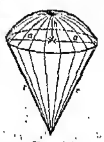

FIG. 78.

Any Spherical Segment. Zone (Fig. 77). Volume $= \frac{1}{6}\pi h(3a^2 + 3a_1^2 + h^2)$. Lateral area (zone) $= 2\pi rh$. Here r = radius of sphere. If the inscribed frustum of a cone be removed from the spherical segment, the volume remaining is $\frac{1}{6}\pi hc^2$, where c = slant height of frustum $= \sqrt{h^2 + (a - a_1)^2}$.

Spherical Sector (Fig. 78). Volume $= \frac{1}{3}r \times$ area of cap $= \frac{2}{3}\pi r^2 h$. Total area = area of cap + area of cone $= 2\pi rh + \pi ra$. Note: $a^2 = h(2r - h)$.

Spherical Wedge bounded by two plane semicircles and a lune. (Fig. 79.) Volume of wedge ÷ volume of sphere $= u/360°$. Area of lune ÷ area of sphere $= u/360°$. u = dihedral angle of the wedge.

Spherical Triangle bounded by arcs of three great circles. (Fig. 80.) Area of triangle $= \pi r^2 E/180°$ = area of octant $\times E/90°$. E = spherical excess $= 180° - (A + B + C)$, where A, B, and C are angles of the triangle. See also p. 134.

Solid Angles. Any portion of a spherical surface subtends what is called a **solid angle** at the center of the sphere. If the area of the given portion of spherical surface is equal to the square of the radius, the subtended solid angle is called a **steradian**, and this is commonly taken as the unit. The entire solid angle about the center is called a **steregon**, so that 4π steradians = 1 steregon. A so-called "solid right angle" is the solid angle subtended by a quadrantal (or trirectangular) spherical triangle, and a "spherical degree" (now little used) is a solid angle equal to $\frac{1}{90}$ of a solid right angle. Hence 720 spherical degrees = 1 steregon, or π steradians = 180 spherical degrees. If u = the angle which an element of a cone makes with its axis, then the solid angle of the cone contains $2\pi(1 - \cos u)$ steradians.

FIG. 79.

FIG. 80.

Regular Polyhedra. A = area of surface; V = volume; a = edge.

Name of solid (see p. 100)	Bounded by	A/a^2	V/a^3

Dodecahedron	12 pentagons	20.6457	7.6631
Icosahedron	20 triangles	8.6603	2.1817

Ellipsoid (Fig. 81). Volume $= \frac{4}{3}\pi abc$, where a, b, c = semi-axes.

Spheroid (or ellipsoid of revolution). The volume of any segment made by two planes perpendicular to the axis of revolution may be found accurately by the prismoidal formula (p. 111).

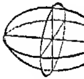

FIG. 81.

FIG. 82.

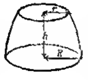

FIG. 83.

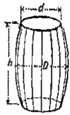

FIG. 84.

Paraboloid of Revolution (Fig. 82). Volume $= \frac{1}{2}\pi r^2 h = \frac{1}{2}$ volume of circumscribed cylinder.

Segment of Paraboloid of Revolution (Bases perpendicular to axis, Fig. 83). Volume of segment $= \frac{1}{2}\pi(R^2 + r^2)h$.

Barrels or Casks (Fig. 84). Volume $= \frac{1}{12}\pi h(2D^2 + d^2)$ approx for circular staves. Volume $= \frac{1}{15}\pi h(2D^2 + Dd + \frac{3}{4}d^2)$ exactly for parabolic staves.

Heater	Bled steam, lb per hr	Replacement factor	Steam added, lb per hr
1st stage	3,740	0.311	1,162
2d stage	3,165	0.485	1,536
3d stage	7,925	0.725	5,750
Total bled	14,830	To be added	8,448

Throttle steam = 56,000 + 8,448 = 64,448 lb/hr.
To condenser = 64,448 − 14,830 = 49,618 lb/hr

This is even closer to the estimated condensate than in the case of the preliminary calculations. A final steam summary can now be made.

Final Steam Summary

	Lb per Hr	
Main propulsion turbines	64,448	
Turbogenerators	3,630	
Total superheated steam		68,078
Evaporators and reciprocating pumps	2,000	
Air ejectors	450	
Total desuperheated steam		2,450
Total steam, all purposes		70,528

This is very close to the 70,500 lb per hr used to estimate the bleeding of the turbine.

From the steam flow diagram (Fig. 1) it can be seen that the turbogenerator steam flow and amount are unchanged. Therefore, start at the main condenser.

From Main Condenser.

	Lb per Hr	
Main propulsion turbines	49,618	
Gland leak-off	−10	
Drain cooler	4,010	
Main intercooler	121	
Through air ejectors	−1

53,738	at	3,221,782
3,700	at	443,800
57,438	at	3,665,582

$$\frac{3{,}665{,}582 \text{ Btu/hr}}{57{,}438 \text{ lb/hr}} = 64 \text{ Btu/lb or } 96 \text{ F}$$

be placed so that it is possible to remove the rotor without removing the frame from the bedplate. Small turbines should be placed so that the top half of the casing and the rotor may be removed without disturbing the rest of the assembly. Sufficient space should be available around boilers and condensers so that tubes can be removed and replaced without disturbing

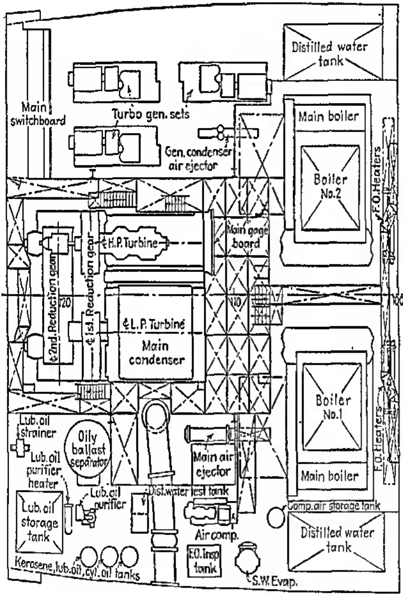

FIG. 5.—Intermediate level of S. S. "Exceller."

other apparatus. Probably the easiest way to assure these features is to make scale-size cardboard cutouts of the various motor and pump assemblies, etc., and have this cutout extended to the point where sufficient space is available to make the repairs mentioned above. Then in the preliminary stages of the layout these cutouts can be moved around and pinned in place temporarily on the layout board. These devices will, of course, show

	Btu per Hr
In condensate	3,665,582
Transferred in drain cooler	260,500
Transferred in first-stage heater	3,710,000
57,438 lb/hr at	7,636,082

$$\frac{7{,}636{,}082 \text{ Btu/hr}}{57{,}438 \text{ lb/hr}} = 133 \text{ Btu/lb or } 165 \text{ F}$$

This enters the deaerating feed heater via the vent condenser at 165 F.

Deaerating Feed Heater and Vent Condenser.

In condensate	57,438 lb/hr	7,636,082 Btu/hr
In bled steam	3,165 lb/hr × 1195 Btu/lb =	3,780,000
Evaporators and reciprocating pumps	2,000 lb/hr × 335 Btu/lb =	670,000
Make-up evaporator	100 lb/hr × 196 Btu/lb =	19,600
Third-stage heater drain	7,825 lb/hr × 319 Btu/lb =	2,500,000
	70,528 lb/hr	14,605,682 Btu/hr

$$\frac{14{,}605{,}682 \text{ Btu/hr}}{70{,}528 \text{ lb/hr}} = 207.5 \text{ Btu/lb or } 239 \text{ F}$$

As 240 F was desired at this point, 239 F is satisfactory.

Third-stage Heater.

7825 lb/hr × 976 Btu/lb	7,650,000 Btu/hr
In condensate	14,605,682
	22,255,682 Btu/hr

$$\frac{22{,}255{,}682 \text{ Btu/hr}}{70{,}528 \text{ lb/hr}} = 316 \text{ Btu/lb or } 345 \text{ F}$$

which was the final feed temperature originally sought.

To determine the fuel consumption, the boiler performance must be calculated.

Boilers.

Enthalpy steam at 615 psia, 810 F	1412.2 Btu/lb
Enthalpy feed water at 345 F	316
Heat gain	1096.2 Btu/lb
Enthalpy steam at 615 psia, 539 F	1245.4
Enthalpy feed water at 345 F	316
Heat gain	929.4 Btu/lb

Superheated 68,078 lb/hr × 1096.2 Btu/lb = 74,600,000 Btu/hr
Desuperheated 2,450 lb/hr × 929.4 Btu/lb = 2,280,000
76,880,000 Btu/hr

Assuming a boiler efficiency of 88 percent and fuel oil with a calorific value of 18,500 Btu per lb, the oil consumption should be

$$\frac{76{,}880{,}000 \text{ Btu/hr}}{0.88 \times 18{,}500 \text{ Btu/lb}} = 4710 \text{ lb/hr fuel}$$

$$\frac{4{,}710 \text{ lb/hr}}{8{,}500 \text{ shp}} = 0.555 \text{ lb fuel/shp/hr}$$

Install two boilers.

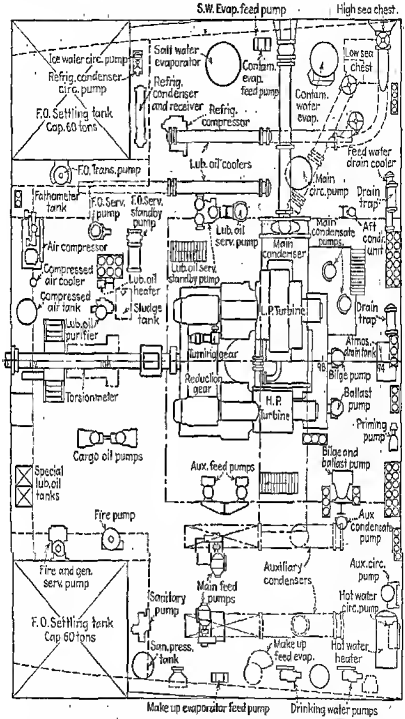

FIG. 6.—Engine-room layout of the S. S. "Joseph Lykes," a 4,000 S.H.P., C-1-B. steamship designed by the U.S. Maritime Commission. (*From Marine Engineering and Shipping Review.*)

ELECTRICAL LOAD AND SIZES OF AUXILIARIES

Fireroom **Blowers.** Assume that three fireroom blowers will be installed any one of which will be able completely to handle the requirements of each of the two boilers. Assume that the total air pressure required is to be 8 in water when 225 cu ft air per lb fuel is being supplied. This is a fair set of operating conditions for modern boilers and is probably on the conservative side.

From the heat balance,

$$\frac{4{,}710 \text{ lb/hr} \times 225 \text{ cu ft/lb}}{60 \text{ min}} = 17{,}700 \text{ cfm}$$

for 2 blowers.

$$\frac{17{,}700}{2} = 8{,}850 \text{ cfm/blower at 8 in. water}$$

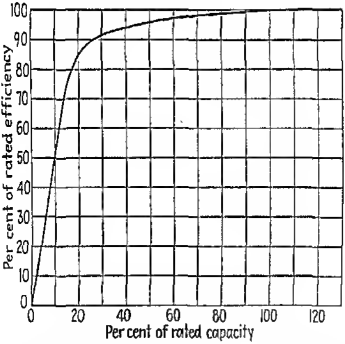

FIG. 4.—Electric motors. Approximate percentage of full load efficiency at fractional loads.

Assume 60 percent blower efficiency. This is a conservative figure, and the manufacturer of the blower may guarantee a higher efficiency.

$$\text{Hp} = \frac{0.0001573 \times \text{cfm} \times \text{in. water}}{\text{efficiency}}$$

$$= \frac{0.0001573 \times 8{,}850 \times 8}{0.60} = 18.6$$

Install a 20-hp 1,750-rpm motor. Table 13, p. 1727, shows the performance to be expected of conventional designs of d-c motors.

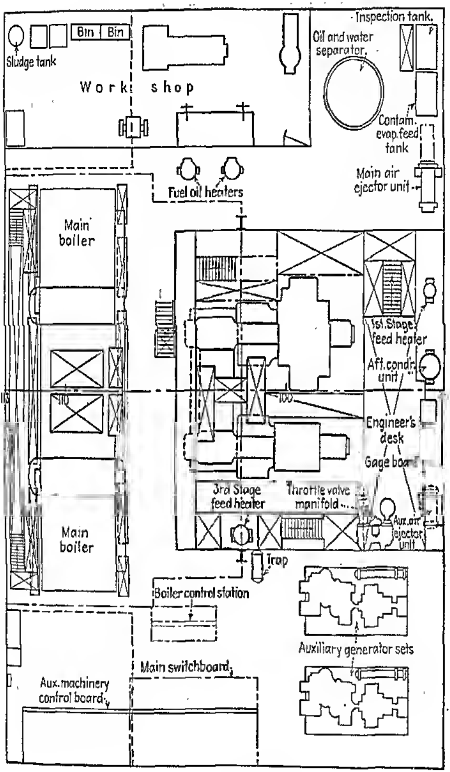

FIG. 6.—*Continued.*

18.6/20 = 94 percent of rated capacity. Efficiency at this load is 87.5 percent (see Fig. 4).

$$\text{Kw input to motor} = \frac{18.6 \times 0.746}{0.875} = 15.9$$

$$\text{Total kw} = 2 \times 15.9 = 31.8$$

Main Circulating Pump. Install one, operate one. Later, the actual water and pressure required for the condenser can be obtained from the condenser manufacturer; at the present stage a preliminary estimate must be made. Assuming 1000 Btu dissipated in the condenser for each pound of turbine exhaust and a 10 F rise in sea water passing through the condenser, which are conservative figures, the Btu per gallon on sea water can be approximated as follows. There are 8.58 lb per gal in sea water under average temperature conditions and the specific heat is 0.94.

0.94 × 8.58 × 10 F = 80.6 Btu/gal
49,618 lb/hr to condenser (see heat balance, p. 1277)

$$\frac{49{,}618 \text{ lb/hr} \times 1000 \text{ Btu/lb}}{80.6 \text{ Btu/gal} \times 60 \text{ min}} = 10{,}300 \text{ gpm}$$

which should be the normal capacity of the pump. Install with 20 percent margin, or 1.2 × 10,300 = 12,380 gpm. Call it 12,500 gpm at 10 psi total head and assume motor drive at 690 rpm. Take 10 psi as equivalent to 23 ft ahead. Make the impeller so as to have water enter each side as in Fig. 1 in the pump section. This would result in 6.250 gpm per side at 23 ft 690 rpm (see Fig. 10, p. 1606). N_s = 5,170 (see Fig. 11, p. 1607). Efficiency = 87 percent. A mix-flo type of pump.

$$\text{Hp} = \frac{\text{gpm} \times \text{psi}}{1{,}715 \times \text{efficiency}}$$

$$\text{Hp} = \frac{12{,}500 \times 10}{1{,}715 \times 0.87} = 83.8$$

Install 85-hp motor capable of speed adjustment down to 75 percent of rated speed by means of shunt field rheostat.

Operating load on the pump is 10,300 gpm or $\frac{10{,}300}{12{,}500}$ = 82.5 percent of rated capacity (see Fig. 12, p. 1608).

$$\text{Efficiency} = 0.95 \times 0.87 = 0.826$$

$$\text{Operating head is} \left(\frac{10{,}300}{12{,}500}\right)^2 (10) = 6.8 \text{ psi}$$

$$\text{Operating hp} = \frac{10{,}300 \times 6.8}{1715 \times 0.826} = 49.4$$

See Table 13, page 1727. Motor efficiency is 0.89. Motor efficiency at 49.4 hp is .87 percent (see Fig. 4).

$$\text{kw input} = \frac{0.746 \times \text{hp}}{\text{efficiency}} = \frac{0.746 \times 49.4}{0.87} = 42.4$$

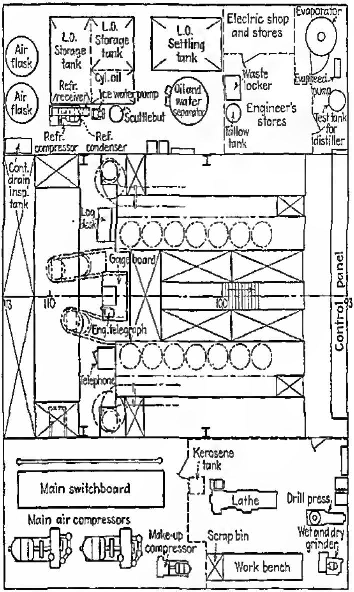

FIG. 7.—Engine-room layout of the S. S. "American Manufacturer," a 4,000 S.H.P., C-1-B. diesel ship designed by the U. S. Maritime Commission. (*From Marine Engineering and Shipping Review.*)

Main Condensate Pumps. Install two, operate one.

$$\frac{53{,}738 \text{ lb/hr}}{8.33 \text{ lb/gal} \times 60 \text{ min}} = 107.4 \text{ gpm}$$

Install with 35 percent margin.

$$1.35 \times 107.4 = 145 \text{ gpm}$$
$$75 \text{ psi total head}$$

Make two stage and drive at 1,750 rpm (see Fig. 10, p. 1606).

$$75 \text{ psi} = 172.5 \text{ ft head}$$
$$\frac{172.5}{2} = 86.25 \text{ ft head per stage}$$
$$N_s = 748 \qquad \text{(See Fig. 11, p. 1607)}$$
$$\text{Efficiency} = 58 \text{ percent}$$
$$\text{Hp} = \frac{145 \times 75}{1{,}715 \times 0.58} = 10.92$$

Install a 12-hp motor. Operating capacity of the pump is $\frac{107.4 \text{ gpm}}{145 \text{ gpm}} = 74$ percent of rated (see Fig. 12, p. 1608).

$$\text{Operating efficiency} = 0.90 \times .58 = 52.2 \text{ percent}$$
$$\text{Operating hp} = \frac{107.4 \times 75}{1{,}715 \times 0.522} = 0$$

See Table 13, page 1727. Full-load efficiency = 86 percent. Motor efficiency at 75 percent load = 85 percent (see Fig. 4).

$$\text{Kw input} = \frac{0.746 \times 9}{0.85} = 7.92$$

Auxiliary Condensate Pumps. One pump for each generator,

$$\text{Full-load water rate} = 12.55 \text{ lb/kwhr}$$
$$350 \text{ kw} \times 12.55 \text{ lb/kwhr} = 4{,}400 \text{ lb/hr}$$
$$\frac{4{,}400 \text{ lb/hr}}{8.33 \text{ lb/gal} \times 60 \text{ min}} = 8.8 \text{ gpm normal}$$

Install with 35 percent margin.

$$1.35 \times 8.8 = 11.9$$

Call it 12 gpm at 75 psi total head. Make two stage and drive at 1,750 rpm.

$$75 \text{ psi} = 172.5 \text{ ft load}$$
$$172.5$$

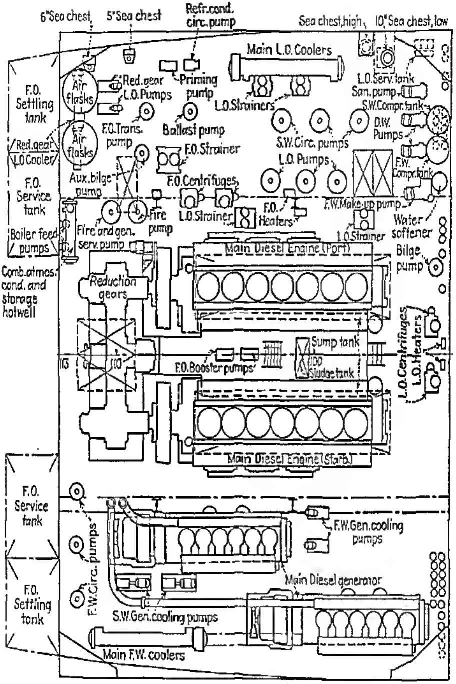

FIG. 7.—*Continued.*

Refer to Fig. 11, p. 1607. This value of specific speed is off the curve, but extrapolation indicates an efficiency of approximately 30 percent.

$$\text{Hp} = \frac{12 \times 75}{1{,}715 \times 0.30} = 1.75$$

Install 2-hp motor. Operating capacity of the pump is $8.8/12 = 73.5$ percent of rated (see Fig. 12, p. 1608). Operating efficiency, $0.90 \times 0.30 = 27$ percent.

$$\text{Operating hp} = \frac{8.8 \times 75}{1{,}715 \times 0.27} = 1.425$$

See Table 13, p. 1727 Motor efficiency, 78 percent. At 1,425 hp, motor efficiency $= 77.5$ percent (see Fig. 4)

$$\text{Kw input} = \frac{0.746 \times 1.425}{0.775} = 1.37$$

Auxiliary Circulating Pumps. One pump for each generator. Assume 1100 Btu per lb dissipated in condenser because of the lower efficiency of the turbogenerator turbine.

$$\frac{4{,}400 \text{ lb/hr} \times 1100 \text{ Btu/lb}}{80.6 \text{ Btu/gal} \times 60 \text{ min}} = 1{,}000 \text{ gpm}$$

Install with 20 percent margin. $1.2 \times 1{,}000 = 1{,}200$ *gpm at 10 psi total* head, 23 ft. Make this small pump of the centrifugal type, single stage, operating at 1,750 rpm (see Fig. 11, p. 1607). Efficiency $= 75$ percent.

$$\text{Hp} = \frac{1{,}200 \times 10}{1{,}715 \times 0.75} = 9.35$$

Install 10-hp motor. 86 percent rated efficiency (see Table 13, p. 1727).

$$\text{Operating pressure} = \left(\frac{1{,}000}{1{,}200}\right)^2 (10) = 7$$

$$\text{Pump operating efficiency} = 0.95 \times 0.75 = 71 \text{ percent}$$

$$\textit{Operating hp} = \frac{1{,}000 \times 7}{1{,}715 \times 0.71} = 5.75$$

Operating motor efficiency $= 83.5$ percent (see Fig. 4)

$$\text{Kw input} = \frac{0.746 \times 5.75}{0.835} = 5.15$$

Main Feed Pumps. *Two installed, two operating.* *70,528 lb per hr* total steam all of which passes through the main feed pump. Weight of water at this temperature is 7.9 lb per gal.

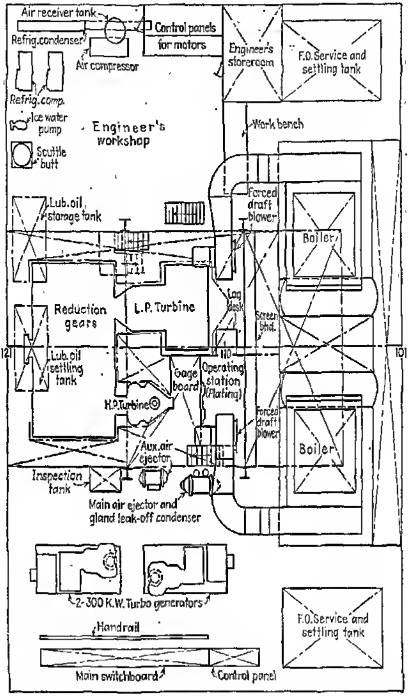

Fig. 8.—Engine-room layout of the S. S. "Hawaiian Planter," an 8,500 S.H.P., C-3 steamship designed by the U. S. Maritime Commission. (*From Marine Engineering and Shipping Review.*)

Boiler drum pressure	640 psia
5% line drop	32 psi
Check valve	50 psi
Economizer	16 psi
3-stage heater	20 psi
Discharge pressure	758 psia
Assume suction pressure	20 psia
Total head	738 psi

$$\frac{70{,}528 \text{ lb/hr}}{7.9 \text{ lb/gal} \times 60 \text{ min} \times 2 \text{ pumps}} = 74.5 \text{ gpm}$$

Install with 25 percent margin.

$$1.25 \times 74.5 = 93 \text{ gpm per pump}$$

Install 100-gpm pumps. Investigation will show that for this small capacity so many stages would be needed to obtain a centrifugal pump with reasonable efficiency that it would be better to use a motor-driver reciprocating pump (see Fig. 32, p. 1627). Use with double reduction gearing.

$$\text{Water hp} = \frac{100 \times 738}{1{,}715} = 43$$

$$\text{Efficiency} = 82 - 5 = 77 \text{ percent}$$

$$\text{Hp input} = \frac{43}{0.77} = 56$$

Install 60-hp motor. 89 percent rated efficiency (see Table 13, p. 1727).

$$\textit{Operating hp} = \frac{74.5 \times 738}{1{,}715 \times 0.77} = 41.6$$

Motor efficiency at 41.6 hp is 87 percent (see Fig. 4).

$$\text{Total kw input} = \frac{2 \times 0.740 \times 41.6}{0.87} = 71.5$$

Fuel-oil Service Pumps. Two installed, one operating. Fuel oil weighs 8.1 lb per gal.

$$\frac{4{,}710 \text{ lb/hr fuel}}{8.1 \text{ lb/gal} \times 60 \text{ min}} = 9.7 \text{ gpm operating}$$

Install with 30 per cent margin.

$$1.3 \times 9.7 = 12.6. \quad \text{Call it } 12.5 \text{ gpm.}$$

Fuel-oil service pumps, regardless of the horsepower or steam pressure of the ship, are usually installed capable of 400 psi total head. This is on account of the atomizing pressure required at the burners (see Fig. 36, p. 1630). Rated efficiency = 62 percent.

$$\text{Hp} = \frac{12.5 \times 400}{1{,}715 \times 0.62} = 4.7$$

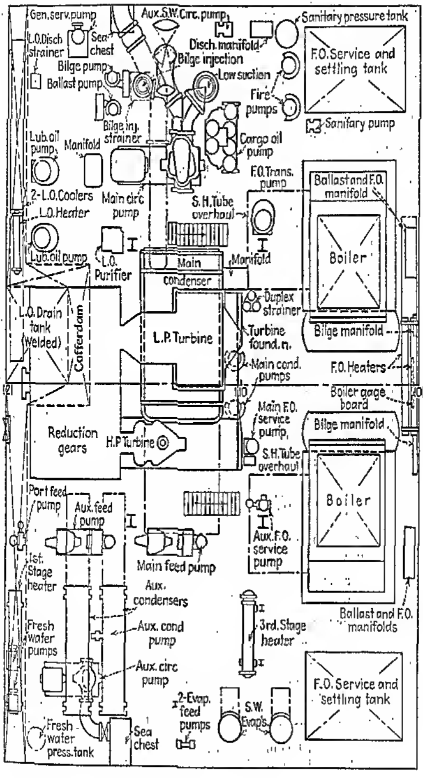

FIG. 8.—*Continued.*

Install 5-hp motor. Rated motor efficiency = 80 percent (see Table 13, p. 1727).

$$\text{Operating capacity of pump} = \frac{9.7}{12.5} = 77.5 \text{ percent}$$

$$\text{Operating pump efficiency} = 1.00 \times 0.62 = 62 \text{ percent}$$

$$\text{Operating hp} = \frac{9.7 \times 400}{1{,}715 \times 0.62} = 3.65$$

Operating motor efficiency 78.5 percent (see Fig. 4).

$$\text{Total kw} = \frac{3.65 \times 0.746}{0.785} = 3.47$$

Lubricating-oil Service Pumps. Two installed, one operating at full capacity. Obtain preliminary capacity from empirical formula.

$$\begin{aligned} \text{Gpm} &= 36 + \sqrt{(7.15)(\text{shp}) + 1{,}300} \\ &= 36 + \sqrt{7.15 \times 8{,}500 + 1{,}300} = 286 \end{aligned}$$

Call it 300 gpm at 50 psi total head (see Fig. 35, p. 1629). Rated efficiency = 71 percent.

$$\text{Hp} = \frac{300 \times 50}{1{,}715 \times 0.71} = 12.3$$

Install 15-hp motor, 87 percent efficiency. At 12.3 hp the efficiency should be approximately the same as at rated capacity.

$$\text{Total kw} = \frac{12.3 \times 0.746}{0.87} = 10.55$$

Total Electrical Load. The total kilowatt load due to these pumps and fans is as follows:

Fireroom blower	31.8
Main circulating pump	42.4
Main condensate pump	7.9
Auxiliary condensate pumps	1.4
Auxiliary circulating pumps	5.2
Main feed pumps	71.5
Fuel-oil service pump	3.5
Lubricating-oil service pump	10.6
	174.3

This compares favorably with the estimate of 175 kw made to cover straight propulsion load. The remainder of the electrical load consisting of bilge pumps, sanitary water pumps, ventilating fans, galley, laundry, etc., and of such items as are not controlled by the propulsion equipment was assumed to be 100 kw. This information should be furnished by the naval architect. Total operating load, 275 kw.

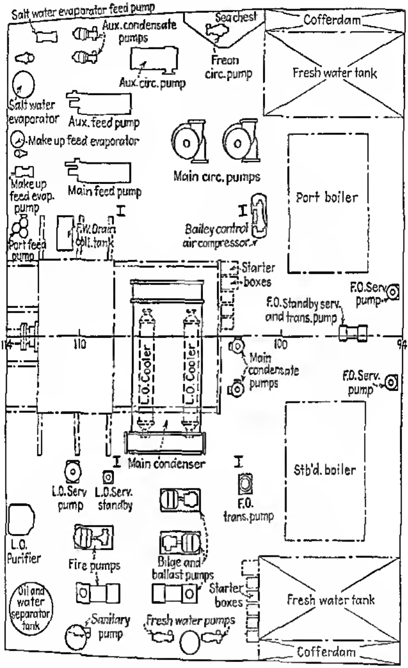

FIG. 9.—Engine-room layout of the S. S. "Robin Locksey," a 6,300 S.H.P. steamship. (*From Marine Engineering and Shipping Review.*)

LAYOUT

General. There are a few fundamental principles that should be followed in machinery layout. The rest is common sense and ingenuity.

1. Apparatus should be accessible for operation, inspection, and repair.
2. Apparatus should be compactly arranged so as to occupy as little space as necessary so as to free space for revenue purposes.

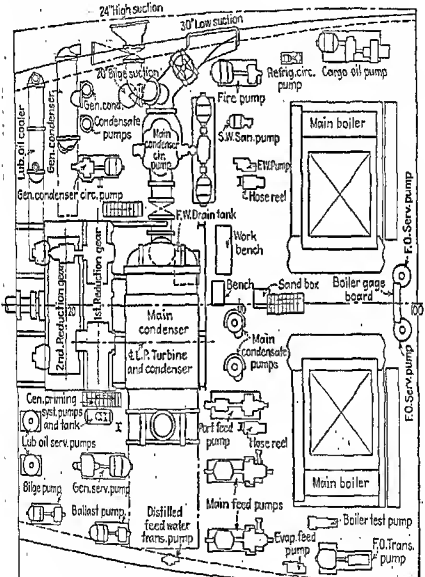

FIG. 5.—Lower level of S. S. "Exceller."

3. Certain types of apparatus should occupy certain relative positions, or they will render the plant inoperative.
4. Apparatus should be so disposed as to assure trim of the ship.

Requirements 1 and 2 are opposed to each other and, as in all successful engineering, the best compromise should be reached. Electric motors should

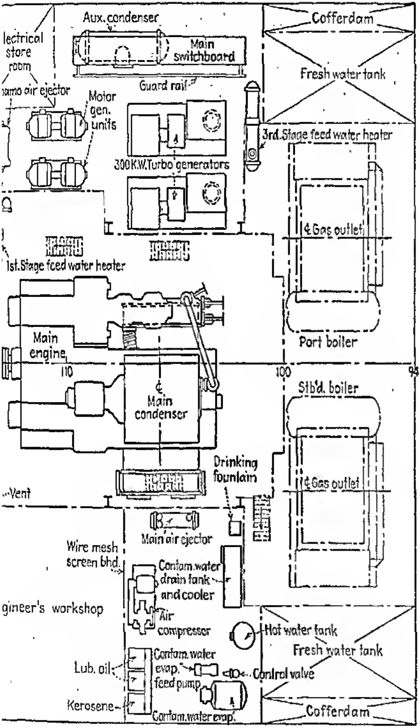

FIG. 9.—*Continued.*

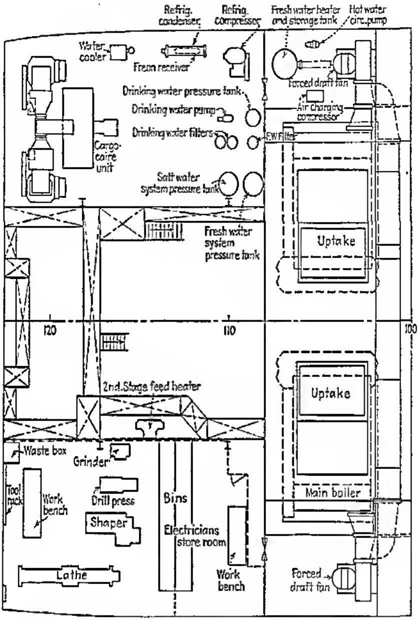

Fig. 5.—Engine-room layout (upper level) of the S. S. "Exceller," a 7,500 S.H.P. steamship. *(From Marine Engineering and Shipping Review.)*

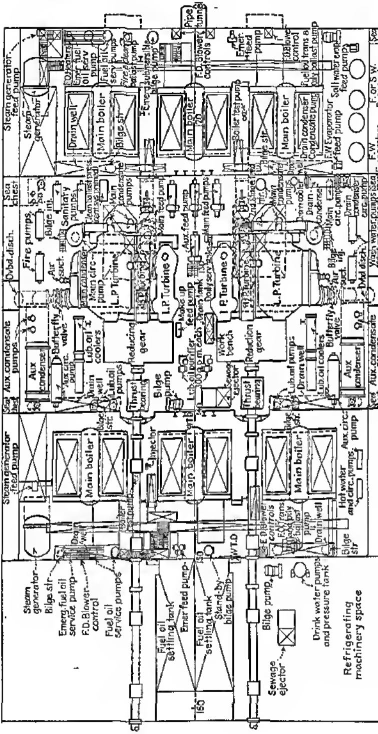

FIG. 10a.—Engine-room layout of the U. S. S. "West Point" (formerly S. S. "America"), a 34,000 S.H.P. steamship. (*From Marine Engineering and Shipping Review.*)

For a standing cask, partially full, compute contents by the prismoidal formula, p. 111. Roughly, the number of gallons, G, in a cask is given by $G = 0.0034n^2h$, where n = number of inches in the mean diameter, or $\frac{1}{2}(D + d)$, and h = number of inches in the height.

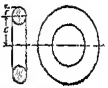

FIG. 85.

Torus, or Anchor Ring (Fig. 85). Volume $= 2\pi^2cr^2$. Area $= 4\pi^2cr$ (Proof by theorems of Pappus).

Theorems of Pappus. 1. Assume that a plane figure, area A, revolves about an axis in its plane but not cutting it; and let s = length of circular arc traced by its center of gravity. Then volume of the solid generated by A is $V = As$. For a complete revolution, $V = 2\pi rA$, where r = distance from axis to center of gravity of A.

2. Assume that a plane curve, length l, revolves about an axis in its plane but not cutting it; and let s = length of circular arc traced by its center of gravity. Then area of the surface generated by l is $S = ls$. For a complete revolution, $S = 2\pi rl$, where r = distance from axis to center of gravity of l.

NOTE. If V_1 or S_1 about any axis is known, then V_2 or S_2 about any parallel axis can be readily computed when the distance between the axes is known.

Generalized Theorems of Pappus. Consider any curved path of length s. If (1) a plane figure, area A [or (2) a plane curve, length l] moves so that its center of gravity slides along this curved path (Fig. 86), while the plane of A [or l] remains always perpendicular to the path, then (1) the volume generated by A is $V = As$ [and (2) the area generated by l is $S = ls$]. The path is assumed to curve so gradually that successive positions of A [or l] will not intersect.

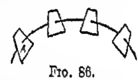

FIG. 86.

The Prismoidal Formula (Fig. 87). Volume $= \frac{1}{6}h(A + B + 4M)$, where h = altitude, A and B = areas of bases and M = area of a plane section midway between the bases. This formula is exactly true for any solid lying between two parallel planes and such that the area of a section at distance x from one of these planes is expressible as a polynomial of not higher than the third degree in x. It is approximately true for many other solids.

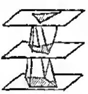

FIG. 87.

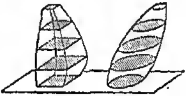

FIG. 88.

Simpson's Rule may be applied to finding volumes, if the ordinates y_1, y_2, be interpreted as the areas of plane sections, at constant distance h apart (p. 106).

Cavalieri's Theorem. Assume two solids to have their bases in the same plane. If the plane section of one solid at every distance x above the base is equal in area to the plane section of the other solid at the same distance x above the base, then the volumes of the two solids will be equal. See Fig. 88.

ALGEBRA

FORMAL ALGEBRA

Notation. The main points of separation in a simple algebraic expression are the $+$ and $-$ signs. Thus, $a + b \times c - d \div x + y$ is to be interpreted as $a + (b \times c) - (d \div x) + y$. In other words, the range of operation of the symbols $\times$ and $\div$ extends only so far as the next $+$ or $-$ sign. As between the signs $\times$ and $\div$ themselves, $a \div b \times c$ means, properly speaking, $a \div (b \times c)$; that is, the $\div$ sign is the stronger separative; but this rule is not always strictly followed, and in order to avoid ambiguity it is better to use the parentheses.

The range of influence of exponents and radical signs extends only over the next adjacent quantity. Thus, $2ax^3$ means $2a(x^3)$, and $\sqrt{2}ax$ means $(\sqrt{2})(ax)$. Instead of $\sqrt{2}ax$, it is safer, however, to write $\sqrt{2}\cdot ax$, or, better, $ax\sqrt{2}$.

Any expression within parentheses is to be treated as a single quantity. A horizontal bar serves the same purpose as parentheses.

The notation $a \cdot b$, or simply ab, means $a \times b$; and $a:b$, or a/b, means $a \div b$.

The symbol $|a|$ means the "absolute value of a," regardless of sign; thus, $|-2| = |+2| = 2$.

The symbol $n!$ (where n is a whole number) is read: "n factorial," and means the product of the natural numbers from 1 to n, inclusive. Thus $1! = 1$; $2! = 1 \times 2$; $3! = 1 \times 2 \times 3$; $4! = 1 \times 2 \times 3 \times 4$; etc.

The symbol $\neq$ or $\not\doteq$ means "not equal to"; $\pm$ means "plus or minus."

The symbol $\approx$ is sometimes used for "approximately equal to."

Addition and Subtraction. $a + b = b + a$.

$(a + b) + c = a + (b + c)$. $a - (-b) = a + b$. $a - a = 0$.

$a + (x - y + z) = a + x - y + z$. $a - (x - y + z) = a - x + y - z$.

A minus sign preceding a parenthesis operates to reverse the sign of every term within, when the parentheses are removed.

Multiplication and Simple Factoring. $ab = ba$. $(ab)c = a(bc)$. $a(b + c) = ab + ac$. $a(b - c) = ab - ac$. Also, $a \times (-b) = -ab$, and $(-a) \times (-b) = ab$; "unlike signs give minus; like signs give plus."

$(a + b)(a - b) = a^2 - b^2$.

$(a + b)^2 = a^2 + 2ab + b^2$, $(a - b)^2 = a^2 - 2ab + b^2$.

$(a + b)^3 = a^3 + 3a^2b + 3ab^2 + b^3$, $(a - b)^3 = a^3 - 3a^2b + 3ab^2 - b^3$; etc.

(See table of binomial coefficients, p. 39; also p. 114.)

$a^2 - b^2 = (a - b)(a + b)$, $a^3 - b^3 = (a - b)(a^2 + ab + b^2)$.

$a^n - b^n = (a - b)(a^{n-1} + a^{n-2}b + a^{n-3}b^2 + \ldots + ab^{n-2} + b^{n-1})$.

$a^n + b^n$ is factorable by $a + b$ only when n is odd; thus,

$a^3 + b^3 = (a + b)(a^2 - ab + b^2)$,

$a^5 + b^5 = (a + b)(a^4 - a^3b + a^2b^2 - ab^3 + b^4)$; etc.

The following transformation is sometimes useful:

$$ax^2 + bx + c = a\left[\left(x + \frac{b}{2a}\right)^2 - \left(\frac{\sqrt{b^2 - 4ac}}{2a}\right)^2\right]$$

Fractions. If m is not zero, $\dfrac{ma + mb + mc}{mx + my} = \dfrac{a + b + c}{x + y}$; that is, both numerator and denominator of a fraction may be multiplied or divided

clearances on the plan view only; further check must be made for vertical clearances.

As to requirement 3, the deaerating feed heaters should be placed at as high a point as possible in order to obtain sufficient head on the feed pumps. If this cannot be done, booster pumps will be necessary. For the same reasons, the feed pumps must be placed at as low a point as possible. Bilge pumps should, of course, be placed at as low a point as possible. Condensers should always be placed directly under the turbines they serve and should be

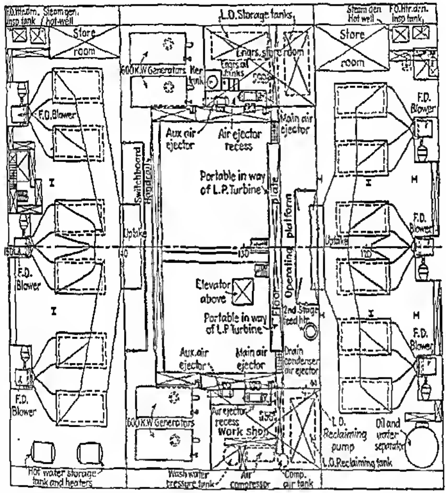

FIG. 10*b*.—Upper level of the U. S. S. "West Point" (formerly S. S. "America"). (*From Marine Engineering and Shipping Review.*)

supported by the turbines. The main propulsion turbines and gears should be so disposed as to have the shortest runs of propulsion shafting and to clear other shafting. The shafting should have as little angle with the center line of the ship as is practical. In the case of a single-screw ship, the propulsion shafting line should coincide with the center line of the ship. A slight angle of elevation is permissible so as to permit the turbines to be above the condenser yet have as great a submergence of the propeller as practical. The tip of the propeller blade must not go below keel.

As to requirement 4, ordinary symmetry of arrangement of the heavier items such as turbines, gears, and boilers will almost solve the problem. A

turbine may be shut down from the deck if desired. This feature is required by the U.S. Coast Guard as a remote means for securing the main turbine if it is necessary to abandon ship and no one is in the engine room to secure the turbine.

Diesel-engine and High-speed Reciprocating-engine Lubricating-oil Service System. Lubricating-oil service systems installed for diesel engines are usually of the pressure type, similar to that installed for a steam turbine-driven vessel. They do differ, however, from the turbine installation in that they require larger quantities of oil at higher pressures at the oil inlet connection than a turbine installation of the same shaft horsepower. In order to maintain constant oil pressure at the engine, the oil delivery is controlled by adjusting the speed of the service pump, which should be fitted for about 50 percent speed control. This wide speed control is necessary since for a constant oil pressure most engines require much more oil at reduced speeds than when operating at full speed. In a diesel installation the oil becomes contaminated with fine carbon particles in a very short time, and these are usually removed by installing a by-pass type of oil filter. These filters employ fuller's earth, or cellulose material, as a filtering medium.

Oil service systems for high-speed reciprocating engines employing forced oil feed are very similar to those installed for steam turbine-driven vessels employing the pressure-type oil system, except that the oil pressure required at the engine is relatively high and the quantity of oil required is much less than for turbines of the same shaft horsepower.

The oil storage, transfer, and purifying systems are the same for diesel and high-speed reciprocating engines except that on diesel installations the oil storage tank must be large to allow for the relatively large amount of oil consumed by the engine.

Piping Materials. The lubricating-oil piping materials, installed on most vessels that have been built to the U.S. Maritime Commission requirements, have used standard-weight black steel pipe with all valves, flanges, and fittings either forged or cast steel. All take-down joints are generally flanged along with all valves 2 in. and above in size. All small sizes of valves and fittings are either of screwed or socket-welded design, with the screwed design of valves seal-welded to the pipe. All fittings 2 in. in size and larger are generally of butt-welded design with a few cast-steel flanged fittings being used where necessary. With the foregoing arrangement, a tight system is assured since all joints are either of welded or flanged design. The use of an all-steel system is an advantage since it offers the maximum protection against a fire hazard due to the high melting point of the steel as compared with copper or brass.

The oil-piping material installed on all new U.S. Navy constructions employs the use of thin-wall steel tubing with all valves, flanges, and fittings either forged or cast steel. All joints are either welded or flanged similar to merchant practice. In the past, however, the Navy used copper tubing with composition valves and fittings, and many of these vessels are still in use today with these materials.

Extreme precaution should be taken at all times from the fabrication of all the parts to the completion of the system, in order to ensure that all foreign matter is removed and has no opportunity to reenter the system. After all piping has been fabricated and fitted into the vessel, it should be disassembled and thoroughly cleaned by sandblasting. The use of pickling in lieu of sandblasting is not generally satisfactory since the pickling will not

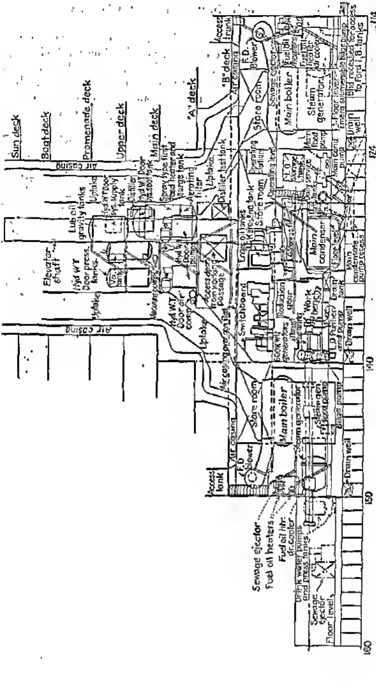

FIG. 10a.—Longitudinal elevation of machinery arrangement in the U. S. S. "West Point" (formerly S. S. "America"). (*From Marine Engineering and Shipping Review.*)

remove the lacquer or varnish usually placed on the steel pipe by the manufacturer. After sandblasting, all of the pipe should be reassembled and flushed with a light grade of flushing oil for a period of about 24 to 48 hr. During this operation, the oil should not pass through the turbine and gears for foreign matter may lodge in the bearings and cause trouble at some later date.

Capacity Service Pumps. It is difficult to determine the actual quantity of oil required to be delivered by the lubricating-oil service pumps, since it varies, depending upon the type of unit involved, the individual ideas of the manufacturer, the shaft horsepower, and the propeller revolutions. As an example of the effect the individual designs of the manufacturer have upon the lubricating-oil requirements it may be noted that for 8,500 shp geared turbine units installed on the U.S. Maritime Commission Victory ships and supplied by three of the leading manufacturers and all operating with the same propeller rpm and steam conditions, the individual oil requirements varied from 230 gpm as a minimum to 310 gpm as a maximum. Therefore, no definite rule can be stated as to the size of pumps required. The accompanying table, however, gives the size required for recent merchant vessels. Pages 1284 and 1633 show a method of estimating capacity required.

Type drive	Normal shp	Propeller rpm	Installed lubricating-oil pump capacity	Installed lubricating-oil pump, T.D.H., psi
Geared turbine	4,000	90	175	50
Geared turbine	6,000	92	250	47
Geared turbine	8,500	85	325	48
Diesel direct	1,700	160	500	50
Diesel direct	6,000	92	375	50

Duplex Strainers. A lubricating-oil duplex strainer is in effect two strainers built into one body, complete with inlet and outlet valves and designed so that one strainer may be in service while the other is available for cleaning. These strainers are of two basic designs. One is the plug type, which employs two plug cock valves for controlling the flow of the oil and the other employs a sliding gate valve. In both designs it is most important that there be some foolproof manner provided to prevent the stoppage of flow when shifting from one compartment to the other at cleaning time. In the case of the plug-type strainer, this feature is obtained by merely interlocking the inlet and outlet plug valves so that they may both work together. With the design of strainer shown in Figs. 5 and 6, an interlocking chain drive is provided between the sliding gate valves. The chain must have sufficient slack so that each individual sliding gate valve may be seated tight by the use of its handwheel. It is also desirable to have an indicator with both the plug and sliding gate valve type of strainer to enable the operator to tell at a glance which compartment is in service and which may be opened for inspection and cleaning. To open the strainer for inspection, generally all that is required is to loosen two or four bolts on the strainer cover; then the cover and strainer basket may be removed.

The materials of the body of a lubricating-oil duplex strainer are generally cast steel, fabricated steel, or a combination of the two. It is best, however, to make the body containing the valve parts, of solid steel casting. Cast

table of moments due to all the apparatus about the centerline of the ship and another table of moments about a line generally somewhat aft of amidships depending upon hull weight distribution should be made up. The moments tending to roll the ship starboard could be called positive and those tending to roll the ship port could be called negative. All these moments should add up to zero. It is a simple matter to shift apparatus, other than

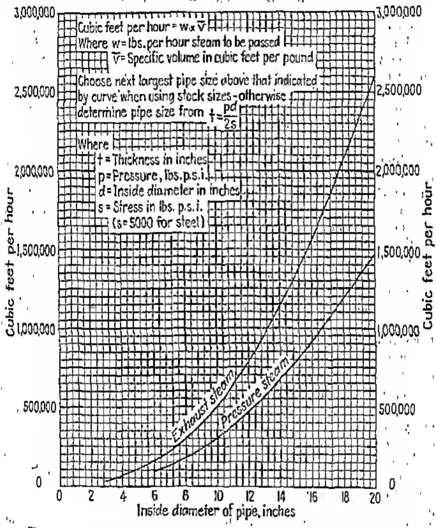

FIG. 11.—Approximate pipe sizes for pressure and exhaust steam.

that covered under requirement 3, so as to obtain a total of zero. In a similar manner the moments about the line aft of amidships should add up to zero. With these tables of moments available any proposal concerning the addition or elimination of apparatus can be disposed of intelligently. Some typical layouts are shown in Figs. 5 to 10.

Figure 11 shows a curve from which the sizes of piping may be determined for both pressure and exhaust steam.

FUEL- AND LUBRICATING-OIL SYSTEMS

BY

ROBERT P. GIBLON

LUBRICATING-OIL SYSTEM

One of the most important parts of the whole marine power plant is the lubricating-oil system. This system may be of a very simple design, such as used with most steam reciprocating engines, where hand lubrication methods with the aid of small tubes and wick feeds are used, or it may be of a more complex design, such as the pressure feed type, as used on turbine, diesel, and some designs of high-speed steam reciprocating engines. The system to be discussed in the next few pages is the pressure feed type, particularly with reference to its use on geared turbine-driven merchant vessels.

Principal Divisions. The lubricating-oil system for a geared turbine-driven vessel is divided into three divisions, the principal one being the **lubricating-oil service system.** The functions of the service system are (1) to supply clean lubricating oil to the main turbins and gear bearings and gear meshes and (2) to remove the heat that is transmitted to the oil from the bearings and gears. The second principal division of the lubricating-oil system is the **storage, transfer, and purifying system,** whose principal functions are (1) to provide storage space for oil that is consumed by the main turbines, turbogenerators, line-shaft bearings, and auxiliary machinery and (2) to provide a method of purifying the oil used by the main turbine and turbogenerator. The third division of the lubricating-oil system is the **turbine governor system,** which operates to protect the turbine from overspeeding and also to shut down the unit immediately should the lubricating-oil service system fail.

Service System. The simplest lubricating-oil system is the pressure type, which is shown by Fig. 1. A system similar to the one shown is used on many merchant vessels. In this system a motor-driven rotary service pump takes suction through a macomb strainer from the turbine and gear sump tank, discharges the oil through a lubricating-oil cooler, a duplex magnetic strainer, and delivers it under pressure directly to the main turbine bearings and gears. The proper distribution of oil to the gears, bearings, and other parts requiring lubrication is accomplished by means of a system of piping, manifolds, and spray nozzles, which are built into the turbine and gear unit. A system of drain piping, also built into the gear unit, carries the oil away from the bearings and gears, back to the oil sump tank. In parallel with the motor-driven service pump is a steam-driven lubricating-oil service stand-by pump, which is installed so that it will operate immediately in event of the failure of the main motor-driven pump and thus prevent damage to the main turbines and gears owing to lack of lubrication. To keep the stand-by pump available for immediate service, it is essential that it be kept operating at an idling speed at all times when the system is in use so that the steam end will remain hot and properly drained. Steam is supplied to the pump for this condition through an orifice fitted in a by-pass around the stand-by pump governor valve. If the service pump should fail, the drop in oil discharge pressure will immediately open the governor valve in the steam supply line and place the stand-by pump in operation. The pump will then deliver

iron may be used, however, if the strainer is to meet only the current 1944 requirements of the American Bureau of Shipping and the U.S. Coast Guard and not the requirements of *Senate Report* 184. The valves are generally bronze with steel stems and handwheels. The strainer baskets are usually bronze and, in the case of a discharge strainer, are lined with bronze or monel wire cloth.

The friction drop and free hole area are two important points to be considered in selecting the size of strainer desired. It is generally considered good practice to have a free hole area through the strainer basket of at least six times the area of the inlet pipe connection, with the velocity of the liquid in the pipe not exceeding approximately 5 fps if the strainer is installed in the suction of a pump, or 6 fps if the strainer is in the discharge side of the pump. To maintain the friction drop as low as possible, it is essential that all ports and passages be as large as possible so that the velocity, and thus friction drop, is maintained at a minimum.

The size of perforations in a strainer depends upon its location and purpose in the system. Strainers located in the suction line to service pumps are used to protect the pump only; therefore, the perforations need to be $\frac{1}{16}$ in. diameter. Small diameter perforations are not recommended for this service since they will present too much resistance to the flow of oil and thus may reduce the capacity of the service pump. Strainers located in the discharge side of the service pump are used to protect the bearings and gears of the engine or turbine from all foreign solid substances. The baskets of these strainers are generally formed of $\frac{1}{16}$ in. thickness plate fitted with $\frac{3}{8}$ in. diameter holes. This basket is then lined with a wire cloth having about 80 wires of 0.004 in. diameter to the inch. The use of any finer mesh is not recommended since it has a tendency to wear very easily.

One of the duplex strainers installed in a lubricating-oil service system should be fitted with magnets effectively clamped in the basket which will remove iron or steel filings, welding beads, or other ferrous material. If bright metal chips are deposited on these magnets, it is a good indication that trouble is developing within the unit being served.

Purifying Lubricating Oil. The entrance of water along with small particles of dirt, rust, and scale into the lubricating-oil system cannot be prevented. These foreign substances, along with solids, formed as a result of decomposition of the oil, should be removed frequently from the lubricating oil. There are three prime methods by which these foreign substances may be removed from oil on shipboard: by settling, by filtering, or by the use of a centrifugal purifier. Generally, a combination of two of the methods or all three are used since each has some feature which the other does not possess.

The use of gravity settling in a tank is the simplest method of purification to employ, but it does not function well at sea owing to the motion of the ship and the relatively long time required to accomplish the settling. The use of filters to purify oil is satisfactory when it is desired to remove only foreign solid substances, but it is not designed for the removal of water from oil. A centrifugal purifier has the advantage over the use of a filter or settling tank, since it will remove both solid foreign substances and liquids in a relatively short time. A filter does, however, tend to remove very fine substances more effectively.

Centrifugal Purifiers. The manner in which separation of two liquids takes place in a centrifugal oil purifier may be easily understood by examining the

enough oil to prevent any damage to the main turbine bearings and gears. To operate the system at its normal pressure conditions, however, the tension of the governor spring should be readjusted by means of a readily accessible handwheel provided on the governor valve.

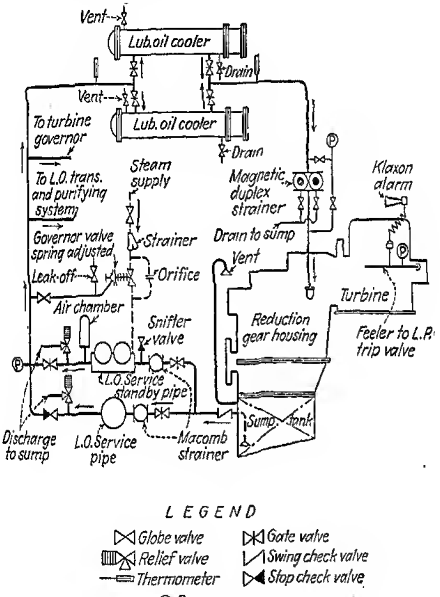

Fig. 1.—Lubricating-oil service system—pressure type.

The gravity-type system, shown by Fig. 2, is similar to the pressure type, except that gravity tanks are fitted in the piping system between the lubricating oil cooler and the turbine and gears. These tanks are generally located about 30 ft above the turbine in order to assure the required pressure at the turbine and gear oil inlet connection. An orifice valve is generally fitted immediately before the inlet connection to allow close adjustment of the oil pressure and flow. The service pump is adjusted to pump oil in excess of that

simplest of all separating devices, the settling tank. Generally speaking, any two liquids that have different specific gravities and are not soluble in each other can be separated by gravity, but they can be separated much more thoroughly and in a fraction of the time by correctly applied centrifugal force.

The primary advantage of a centrifugal purifier over a gravity tank is that it makes use of a force many thousands of times stronger than gravity. When applied to the best advantage, as in the purifying member of either of the designs of purifier shown (see Figs. 7 and 8), centrifugal force is so much more intense than gravity that it will often accomplish work that gravity separation alone would not be able to do. A cubic inch of oil at the bottom of a water-filled tank has a buoyant force of a fraction of an ounce acting on it tending to make it rise to the top. If the same cubic inch of oil were in the purifying member of a separator, the buoyant force would be a good many pounds, enabling separation to be effected in a much shorter time. Moreover, it sometimes happens, as in the case of an emulsion, that a heavy liquid is distributed through a lighter liquid in such very fine droplets that the use of force of gravity cannot cause perceptible movement. Under the influence of centrifugal force, these fine droplets will move and separate out. In addition to separating water from oil, the centrifugal purifier will also remove solid substances. A portion of the solid substances separated is generally removed from the machine along with the water; however, a portion of the solid substances remains in the purifying member and must be removed by hand cleaning methods.

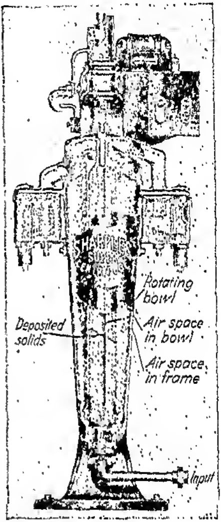

FIG. 7.—Sharples centrifugal oil purifier.

Types of Centrifugal Purifiers. Two common designs of marine lubricating-oil purifiers are shown in Figs. 7 and 8, one of which is the Sharples design and the other the DeLaval design. Each, when installed on shipboard, is fitted with suction and discharge pumps which are capable of lifting oil from one reservoir and discharging it to another. In the Sharples design an additional motor is required to drive the transfer pumps (motor and transfer pumps not shown). On the DeLaval design shown, the attached transfer pumps and centrifuge are all driven by one motor. In the two designs of centrifuges shown, the same principle is employed to accomplish the separating, but the design of the units is quite different, for the Sharples design

required by the turbines and gears, and this excess oil runs through the overflow fitted in the gravity tank and then by a sight glass to the sump tank.

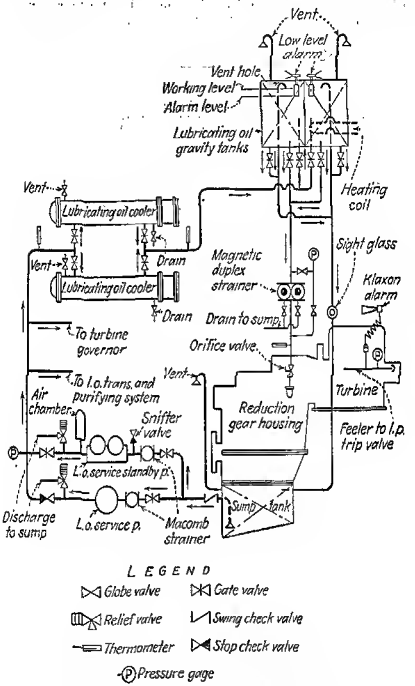

FIG. 2.—Gravity-type lubricating-oil system.

The gravity tanks are generally sized such that there will be about a 3- to 4-min reserve supply that may be used by the main unit after the service pump

employs the use of "tubular-type" bowl, while the DeLaval uses the "disk-type" bowl. The tubular-type bowl is relatively small in diameter, which permits operation at a high rotative speed, which in turn develops high centrifugal force. Also, with the bowl designed with a length many times the depth of the liquid layer, the distance the oil has to travel is many times the settling distance. This allows for a relatively long settling time. In addition, the bowl is provided on the inside with a simple three-wing device,

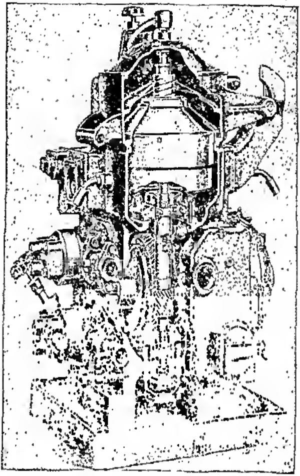

Fig. 8.—De Laval centrifugal oil purifier.

whose function is to keep the liquid up to the speed of the bowl without slipping. The disk-type bowl (see Figs. 8 and 9) is characterized by a relatively larger diameter and by a series of disks that separate the liquid into thin layers and thus creates shallow settling distances. It is general knowledge that in gravity settling, shallow vessels work more rapidly and effectively than deep vessels, since with deep vessels, the particles to be separated have a greater distance to travel before they reach the bottom of the vessel; therefore, more time is required. In the bowl of the centrifuge, the same conditions exist, and both designs tend to employ this principle. In the

ceases to deliver oil. With this reserve supply on hand, sufficient time is usually available to start the steam stand-by pump and prevent damage to the bearings. Gravity tanks are sometimes arranged with a water drain-off connection so that the tank not in use may be used for gravity settling if desired.

In both system designs, it is most important that consideration be given to the location of the lubricating-oil service pumps so that their suction lift is not greater than that for which they are designed, especially when the vessel is not on even keel. The suction pipe in the sump tank should be bell-mouthed and located where it will have not less than ½ ft oil over the open end when the vessel is rolling about 45 deg. The suction piping should be free from bends and of large diameter to assure minimum drop. The macomb strainer indicated in the suction line to the motor-driven service pump is sometimes replaced by a strainer built into the pump suction, which reduces the friction drop in the piping.

On both designs indicated, two lubricating-oil coolers have been shown, since the installation of two units is the most common commercial practice. On many installations, however, only one cooler with an oil by-pass is provided.

The location chosen for the magnetic duplex strainers is a very important item. These strainers should be placed as close to the turbine and gear inlet connection as possible for it should be remembered that the turbine and gears are being protected from foreign matter and not the gravity tanks, oil coolers, or interconnecting piping.

The pressure and gravity systems have certain advantages and disadvantages, and it is a matter of much discussion as to which system is the better to install on a particular design of vessel.

The principal advantages of the gravity system over the pressure system are as follows: (1) In the event of failure of the service pump, about 3 to 4 min are available to restore the flow of oil by the use of the stand-by pump before damage may be done to the main unit. In the pressure system, however, one depends entirely upon the automatic starting of the stand-by pump, which is not considered very dependable by some designers and operators. (2) Close regulation of the oil quantity delivered by the service pump is not required since all excess oil flows through the overflow fitted in the gravity tank. (3) The sight glass provided in the overflow gives a visible indication that sufficient oil is being supplied to the main turbine unit.

The principal advantages of the pressure system over the gravity system are as follows: (1) The pressure system lends itself well to a vessel that has low headroom in the engine room, such as a destroyer or other naval vessel. (2) The fire hazard is greatly reduced since 3,000 to 4,000 gal less of lubricating oil are carried in the engine room. This is particularly an advantage in wartime. (3) The weight of the piping, tanks, etc., for a pressure system is about 50 percent less than that of the gravity system. (4) The installation of a pressure system is almost a requisite for lubrication of high-speed steam reciprocating or diesel engines owing to the relatively high pressure required at the bearings. (5) The size of the lubricating-oil coolers and pumps is smaller than in the gravity system.

Storage, Transfer, and Purifying Systems. The principal tanks installed in the lubricating-oil system are a storage tank, a settling tank, a sump tank, and, in the case of a gravity system, one or two gravity tanks. The storage tank is generally sized sufficiently large to hold one complete fresh charge of lubricating oil for the service system, plus the

Sharples design the bowl is belt-driven from the motor and is suspended by a flexible spindle from a bearing at the top of the housing; in the DeLaval design the bowl is ordinarily gear-driven from below, with the spindle itself rigid but the upper bearing flexibly mounted. The feed to the tubular-type bowl is through a feed nozzle at the bottom, whereas the disk-type bowl is ordinarily fed from the top through a center tube, by which the liquid is directed toward a series of holes punched through the disk stack and then flows upward through these holes. Separated light liquid moves toward the center to discharge into one of the covers, and the separated heavier liquid moves

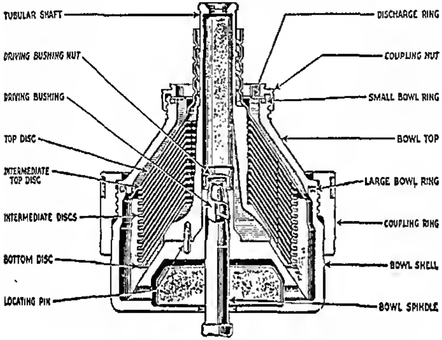

FIG. 9.—Bowl for De Laval centrifugal purifier.

toward the outside, being diverted from the bowl into the other cover (see Fig. 9).

FUEL-OIL SYSTEM

The duty of the fuel-oil service system is to deliver a required quantity of fuel oil at the desired pressure and temperature conditions, to the burners of a boiler in the case of a steam-propelled vessel, or to the injectors of the engine in the case of a diesel-propelled vessel. The system must also be fitted with the necessary filters, strainers, purifiers, etc., so that the oil is delivered in the required purity.

Service System for Steam-propelled Vessels. The system to be discussed is the type that is installed on many steam-propelled merchant vessels that use heavy-grade bunker oil as fuel, since this is the common design. Figure 10 shows a typical fuel-oil service system. In this system, oil may be drawn from either of the two fuel-oil settling tanks or direct from the inner bottom or deep bunker oil tanks. Each settling tank generally has sufficient capacity for about a 28-hr fuel supply for the vessel when it is operating at normal power. For normal operation of the system, oil is pumped by means of a fuel-oil transfer pump (not shown in sketch) from the

oil that will be consumed by the engines during the voyage. The settling and sump tanks generally are sized sufficiently large to take all the oil in the service system. The gravity tanks, when used, usually have a capacity of about 3- to 4-min supply of oil for the normal requirements of the service system.

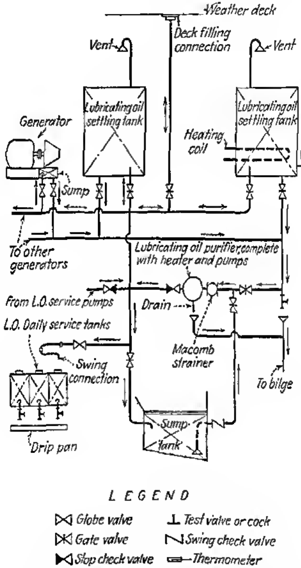

FIG. 3.—Lubricating-oil storage, transfer, and purifying system.

Figure 3 shows a typical piping arrangement for a lubricating-oil storage, transfer, and purifying system. The storage system is designed so that oil from deck may be led to the storage tank where it may be run by gravity to the main or turbogenerator sump tanks. The transfer part of the system is designed so that oil may be pumped from the main sump tank by means of the lubricating-oil purifier transfer pumps and/or the stand-by lubricating-

inner bottom and/or deep fuel-oil storage tanks to the fuel-oil settling tank that is empty. After the tank is filled, it is heated to about 100 to 115 F by means of the tank heating coil provided. The exact temperature to which the oil should be heated depends upon its viscosity characteristics. The oil is then left in the tank for about one day, and water and sediment are allowed

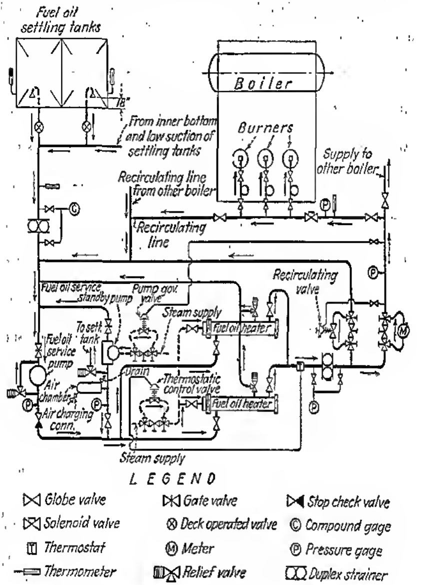

FIG. 10.—Fuel-oil service system for steamships.

to settle. While settling is taking place in the one tank, the service pump will be taking suction from the other tank. When the tank on which the service pump is operating becomes nearly empty, the suction to the full tank is opened and the suction to the empty tank is closed. The empty tank is then filled as described above. For most economical operation, the fuel-oil

oil service pump. These pumps are fitted so that they can discharge either to the storage or settling tanks or to deck. If the turbogenerator sump tanks are to be emptied, the lubricating-oil transfer pumps attached to the purifier may be used or the oil may be run by gravity to the main turbine sump tank.

The purification system is arranged so that either "continuous" or "batch" purification methods may be employed. To accomplish this, a centrifugal lubricating-oil purifier with attached suction and discharge pumps, a lubricating-oil heater, and a lubricating-oil settling tank fitted with a heating coil are generally provided. For continuous purifications, suction is taken from the main turbine sump by means of the purifier suction pump, and oil is discharged through the lubricating-oil heater to the centrifuge where it is purified. The discharge pump takes suction from the purifier and discharges purified oil back to the sump tank. The same operation may be performed for the oil in the turbogenerator sump tanks if desired. The lubricating-oil purifier is generally of sufficient capacity so that it need operate only about 8 hr per day while the vessel is in operation.

For batch purification, suction is taken from the main turbine sump by means of either the lubricating-oil service stand-by pump or the lubricating-oil purifier transfer pumps, and discharged to the lubricating-oil settling tank. Fresh oil may then be run from the storage tank to the sump tank if desired. The oil in the settling tank may then be heated to approximately 180 deg by means of the steam coil provided, and the water will settle from the oil. When the settling has been completed, the water may be drawn off by means of the drain-off valve provided, and then the oil may be run to the centrifuge and purified. The purified oil may then be discharged to the main sump or storage tank depending on whether or not a new charge is desired in the service system. Purification by the centrifuge after settling is not required since the settling tank alone will purify the oil very well.

Purification by the batch method has one serious limitation, however, for it cannot be used unless the main turbines are shut down for the period when the sump tank is empty. The batch method, therefore, is the common one to use when the vessel is in port and the continuous method is the common one to use when at sea.

Turbine Governor System. The turbine governor system is designed primarily to protect the turbines, rotors, and other parts from damage due to overspeeding or from damage to the bearings and gears due to an insufficient supply of lubricating oil. Figure 4 shows a typical governor system. The design shown is similar to that used on many of the Victory ships built for the U.S. Maritime Commission. The sketch shown employs a Westinghouse Electric and Manufacturing Company design of throttle valve manifold complete with its attached oil-operated governing mechanism.

The overspeed protection is obtained by the use of the governor mechanism in the manifold, which is actuated by a small oil pump attached to the turbine shaft. This pump may be of the centrifugal or gear type. In the manifold is fitted a small spring-loaded piston upon which the discharge pressure from the pump acts. This piston moves an oil pilot valve which in turn regulates the oil flow to the large spring-loaded oil piston used to move the steam throttle valve. The oil used for operating the main piston is obtained from the discharge line from the main lubricating-oil service pumps. Thus, if the turbine should overspeed beyond a predetermined figure, the increased oil discharge pressure from the turbine pump will actuate the oil pilot valve. This in turn will dump the oil that holds the main piston in the normal

service pumps are generally of two designs, one being a motor-driven positive-displacement pump and the other a steam reciprocating duplex or simplex pump. The fuel-oil pumps are usually sized to have a capacity at least 10 percent in excess of the maximum oil required to be pumped. The motor-driven service pump is generally fitted for about a 25 to 50 percent speed control with the control rheostat located at the boiler operating station.

Oil from the settling tank is pumped by means of the service pumps through the suction main, a coarse-mesh duplex suction strainer, and is discharged into the service main. The discharge pressure required depends upon the quality of oil to be burned and the type of burner used. The discharge pressure is usually from 125 to 350 lb gage. The oil, after entering the discharge line, is pumped through a fuel-oil heater, a fine-mesh duplex strainer, a meter, and then to the burners.

To control the supply pressure to the burner or to the combustion control valve, when a motor-driven service pump is used, a back-pressure valve is fitted. This back-pressure valve should be located so that all oil pumped will pass through the fuel-oil heaters and so that it may be easily adjusted by the operating personnel. The accessibility of the valve is especially important if an automatic combustion control is not provided and hand operation is required.

In most cases, the steam reciprocating pump is fitted with a steam governor valve that is actuated by the oil discharge pressure. In order to smooth out the pump pulsations created by the reciprocating pump, a large air chamber must be fitted. This chamber should have a capacity of about 4 or 5 cu ft and should be fitted with an air charging and a drain connection.

Both service pumps must be fitted with relief valves and, in the case of the steam reciprocating pump, this valve must be installed so that its discharge will be connected to the settling tank. This is necessary since a reciprocating pump can build up a very high discharge pressure, if both the suction and the discharge valves on the liquid end are closed and the steam pump piston should move, owing to small steam leakages. Many fuel-oil service pumps have been damaged owing to improper connection of the relief valve. Each fuel-oil heater should be fitted with a relief valve which will protect the unit from excessive pressure due to expansion of the oil when both the inlet and the outlet valves are secured and steam is accidentally applied to the unit.

If good combustion is desired, accurate control of the fuel-oil temperature is required. This is imperative since small changes in temperature produce a relatively large change in the quantity of oil burned. This is especially true if an automatic combustion control is fitted since its successful operation depends upon a known quantity of oil being burned for a predetermined oil pressure.

The solenoid valve shown on the sketch is installed if a motor-driven fan is fitted to cut off the supply of oil to the burners in the event of loss of air supply to the boiler. This valve is interlocked electrically with the forced- or induced-draft motor fan, so that if it stops the solenoid valve will close. This valve should also be fitted with a manual quick-closing feature. The installation of this valve is a great help in preventing furnace explosions. If the fan is steam-driven, the solenoid valve should be replaced by a quick-closing valve.

The location and arrangement of the fuel-oil suction piping should be given careful consideration when designing a fuel-oil system for it is necessary that the pressure drop be kept to a minimum. The fuel-oil service pumps

operating position to the sump tank. The main oil piston will then move down owing to the spring loading pressure and close the throttle valve.

For testing the overspeed mechanism, it is not necessary to overspeed the turbine, since a simulated overspeed condition will be obtained if the test valve installed in the governor oil pump return line is opened. Opening this valve creates an increased differential pressure on the oil pilot valve piston since it reduces the back pressure on the oil return line, thereby simulating increased supply pressure or overspeeding.

To protect the turbine and gear bearings and the gear meshes from an insufficient supply of lubricating oil, the governing mechanism is also designed

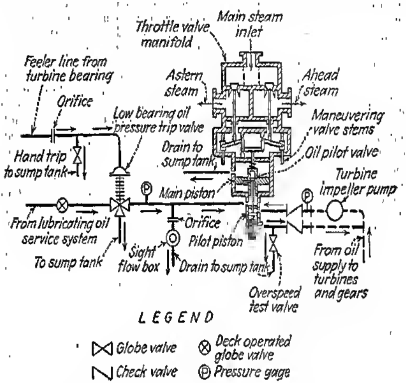

FIG. 4.—Westinghouse turbine governor system.

to cut off the steam to the turbine in the event that (1) the lubricating-oil service pump stops, (2) the oil pump discharge pressure drops below approximately 15 to 20 psi gage, or (3) the bearing oil pressure at the turbine is insufficient. These features are obtained since the main oil piston which operates the steam throttle valve is held open by the oil discharged from the service pump (see Figs. 1 and 2). Thus, if the oil discharge pressure at the pump drops, the spring will move down the main oil piston and cut off the steam supply. The three-way trip valve is installed to cut off the oil supply to the governor in the event that the oil pressure at the turbine bearings drops below a predetermined figure (usually from 5 to 7 psi gage). The operation of both the three-way trip valve and the governor valve may be tested by opening the hand trip valve, which will simulate a low bearing oil pressure.

The deck-operated valve indicated in the sketch is provided so that the

should be located so that they have the minimum static suction lift and so that the suction piping will be as short as possible. All piping should be of ample size, and all valves should be of the gate type. This is a particularly important item if wide-range burners are employed which return hot oil to the pump suction.

The system design shown in the sketch is satisfactory for the use of straight mechanical-pressure atomizer-type burners or wide-range burners not requiring the use of return oil. If it is desired to install a system employing the wide-range burners requiring return oil, the arrangement shown should be modified to install the necessary piping to return the excess oil from the burners back to the pump suction. The fuel-oil meter should be relocated to the suction side of the service pump so that it measures only the oil burned. To arrange the system shown for automatic combustion control, it is merely necessary to add an additional control valve in the oil supply line to each boiler. Several designs of combustion control are in use today on commercial vessels, the most common of which are manufactured by the Bailey Meter Company, Mason-Neilan Regulator Company, General Regulator Company, and Hagan Corporation.

Service System for Diesel-propelled Vessels. The fuel-oil service system for a diesel-propelled vessel is quite different from that used on an oil-burning steam vessel since all oil delivered to the engine must be run through centrifugal purifiers and filters. On a diesel vessel, two daily service tanks are installed, in addition to the two settling tanks. Oil is settled in the settling tanks the same as on a steam-propelled vessel, except that instead of pumping the oil from the settling tanks direct to the engine, the oil is delivered from the settling tank to a centrifugal oil purifier where it is purified and returned to the oil service tanks. The design of centrifuge employed is the same as that employed for lubricating oils. For a detailed description see p. 1311. Oil is then pumped from the service tank by the fuel-oil service pump similar to the system installed on a steam-propelled vessel, except the discharge pressure of the service pump is relatively low, being only from 30 to 50 lb gage. All oil delivered by the service pump must be pumped through a metal edge strainer and a filter, for all oil delivered to the engine must be of the utmost purity. The oil that is delivered by the service system is then handled by the engine injector where it is metered and injected into the cylinders at a high pressure. The oil pressure to the engine is maintained by the use of a back-pressure valve located in the fuel-oil header at the engine. All oil passing through the back-pressure valve is returned to the pump suction.

Piping Materials. The oil piping materials, installed in the suction piping lines to the fuel-oil service pumps on most vessels that have been built for the U.S. Maritime Commission and to meet *Senate Report* 184 requirements, have employed standard-weight black steel pipe with all valves and fittings either forged or cast steel. All take-down joints should be flanged along with all valves 2 in. and above in size. All small sizes of valves and fittings are either of screwed or socket-welded design with the screwed design of valve seal-welded to the pipe. All fittings 2 in. in size and larger are generally of butt-welded design with a few steel-flanged fittings being used where necessary. With the design of system described above, a tight system is assured since all joints are either of welded or flanged design. If the vessels being constructed do not have to meet the requirements of *Senate Report* 184, then cast-iron, bronze, and malleable-iron valves and fittings may be installed in the suction piping. It is best, however, to make all cast-iron valves and

by any quantity different from zero, without altering the value of the fraction.

To add two fractions, reduce each to a common denominator, and add the numerators: $\frac{a}{b}+\frac{x}{y}=\frac{ay}{by}+\frac{bx}{by}=\frac{ay+bx}{by}$.

To multiply two fractions: $\frac{a}{b}\times\frac{x}{y}=\frac{ax}{by}$; $\frac{a}{b}\times x=\frac{a}{b}\times\frac{x}{1}=\frac{ax}{b}$.

To divide one fraction by another, invert the divisor and multiply:

$$\frac{a}{b}\div\frac{x}{y}=\frac{a}{b}\times\frac{y}{x}=\frac{ay}{bx};\quad \frac{a}{b}\div x=\frac{a}{b}\times\frac{1}{x}=\frac{a}{bx}$$

Ratio and Proportion. The notation $a:b::c:d$, which is now passing out of use, is read: "a is to b as c is to d," and means simply $(a/b) = (c/d)$, or $ad = bc$. a and d are called the "extremes," b and c the "means," and d the "fourth proportional" to a, b, and c. The "mean proportional" between two numbers is the square root of their product; also called the "geometric mean" of the numbers (p. 115). If $a/b = c/d$, then $(a+b)/b = (c+d)/d$, and $(a-b)/b = (c-d)/d$; whence also, $(a+b)/(a-b) = (c+d)/(c-d)$. If $a/x = b/y = c/z = \ldots = r$, then

$$(a+b+c+\ldots)/(x+y+z+\ldots)=r$$

Variation. The notation $x \propto y$ is read: "x varies directly as y," or "x is directly proportional to y," and means $x = ky$, where k is some constant. To determine the constant k, it is sufficient to know any pair of values, as x_1 and y_1, which belong together; then $x_1 = ky_1$, and hence $x/x_1 = y/y_1$, or $x = (x_1/y_1)y$. The expression "x varies inversely as y," or "x is inversely proportional to y," means that x is proportional to $1/y$, or $x = k/y$.

Exponents. $a^{m+n} = a^m a^n$. $a^{m-n} = a^m/a^n$. $a^0 = 1$ (if $a \neq 0$). $a^{-m} = 1/a^m$. $(a^m)^n = a^{mn}$. $a^{1/n} = \sqrt[n]{a}$. Thus: $a^{1/2} = \sqrt{a}$, and $a^{1/3} = \sqrt[3]{a}$. $a^{m/n} = \sqrt[n]{a^m}$. Thus: $a^{2/3} = \sqrt[3]{a^2}$ and $a^{3/2} = \sqrt{a^3}$. $(\sqrt[n]{a})^n = a$. $(ab)^n = a^n b^n$. $(a/b)^n = a^n/b^n$. $(-a)^n = a^n$ if n is even. $(-a)^n = -a^n$ if n is odd. If n is positive and increases indefinitely, a^n becomes infinite if $a > 1$, and approaches 0 if $a < 1$ (a being always positive). Graphs, p. 174; series, p. 160.

Radicals. Except in the simple cases of square root and cube root, radical signs should always be replaced by fractional exponents: $\sqrt[n]{a} = a^{1/n}$. $(\sqrt[n]{a})^n = (a^{1/n})^n = a$. If n is odd, $\sqrt[n]{-a} = -\sqrt[n]{a}$; but if n is even, $\sqrt[n]{-a}$ is imaginary. Every positive number a has two square roots, one positive and the other negative; but the notation $\sqrt{a}$ always means the positive root; thus, $\sqrt{9} = 3$; $-\sqrt{9} = -3$. If the denominator of a fraction is of the form $\sqrt{a} \pm \sqrt{b}$, it is possible to "rationalize the denominator" by multiplying both numerator and denominator by $\sqrt{a} \mp \sqrt{b}$. Thus:

$$\frac{\sqrt{a}+\sqrt{b}}{\sqrt{a}-\sqrt{b}}=\frac{(\sqrt{a}+\sqrt{b})(\sqrt{a}+\sqrt{b})}{(\sqrt{a}-\sqrt{b})(\sqrt{a}+\sqrt{b})}=\frac{a+b+2\sqrt{ab}}{a-b}$$

Logarithms. (For the use of logarithms in numerical computation, see p. 91.) The logarithm of a (positive) number N is the exponent of that power to which the base (10 or e) must be raised to produce N. Thus, $x = \log_{10} N$ means that $10^x = N$, and $x = \log_e N$ means that $e^x = N$. Logarithms to base 10 are called **common, denary,** or **Briggsian** logarithms. For table of 4-place common logarithms see pp. 40–43.

Logarithms to base e are called **hyperbolic, natural,** or **Napierian** logarithms. Here $e = 1 + 1 + 1/2! + 1/3! + 1/4! + \ldots = 2.7182818284\,59\ldots$ For table of 4-place hyperbolic logarithms see pp. 58, 59.

If the subscript 10 or e is omitted, the base must be inferred from the context, the base 10 being used in numerical computation, and the base e in theoretical work. In either system,

$$\log (ab) = \log a + \log b \qquad \log (a^n) = n \log a \qquad \log 0 = -\infty$$
$$\log (a/b) = \log a - \log b \qquad \log (\sqrt[n]{a}) = (1/n) \log a \qquad \log 1 = 0$$
$$\log (1/n) = -\log n \qquad \log (\text{base}) = 1 \qquad \log \infty = \infty$$

The two systems are related as follows:

$$\log_{10} e = M = 0.4342944819\ldots; \quad \log_e 10 = 1/M = 2.3025850930\ldots$$
$$\log_{10} x = 0.4343 \log_e x; \qquad \log_e x = 2.3026 \log_{10} x.$$

For tables of multiples of M and $1/M$, see p. 62. For graphs of the logarithmic and exponential functions, see p. 174; series, p. 160.

The Binomial Theorem. (For table of binomial coefficients, see p. 39 and p. 116.)

Let $(n)_1 = n$, $(n)_2 = \dfrac{n(n-1)}{1 \times 2}$, $(n)_3 = \dfrac{n(n-1)(n-2)}{1 \times 2 \times 3}$,

$$(n)_4 = \frac{n(n-1)(n-2)(n-3)}{1 \times 2 \times 3 \times 4}, \ldots$$

Then, for any value of n, provided $|x| < 1$,

$$(1 + x)^n = 1 + (n)_1 x + (n)_2 x^2 + (n)_3 x^3 + (n)_4 x^4 + \ldots$$

(If n is a positive integer, the series breaks off with the term in x^n, and is valid without restrictions on x, see p. 112.)

The most useful **special cases** are the following:

$$\sqrt{1+x} = (1+x)^{1/2} = 1 + \frac{1}{2}x - \frac{1}{8}x^2 + \frac{1}{16}x^3 - \frac{5}{128}x^4 + \ldots \quad (|x| < 1)$$

$$\sqrt[3]{1+x} = (1+x)^{1/3} = 1 + \frac{1}{3}x - \frac{1}{9}x^2 + \frac{5}{81}x^3 - \frac{10}{243}x^4 + \ldots \quad (|x| < 1)$$

$$\frac{1}{1+x} = (1+x)^{-1} = 1 - x + x^2 - x^3 + x^4 - \ldots \quad (|x| < 1)$$

$$\frac{1}{\sqrt{1+x}} = (1+x)^{-1/2} = 1 - \frac{1}{2}x + \frac{3}{8}x^2 - \frac{5}{16}x^3 + \frac{35}{128}x^4 - \ldots \quad (|x| < 1)$$

$$\frac{1}{\sqrt[3]{1+x}} = (1+x)^{-1/3} = 1 - \frac{1}{3}x + \frac{2}{9}x^2 - \frac{14}{81}x^3 + \frac{35}{243}x^4 - \ldots \quad (|x| < 1)$$

$$\sqrt{(1+x)^3} = (1+x)^{3/2} = 1 + \frac{3}{2}x + \frac{3}{8}x^2 - \frac{1}{16}x^3 + \frac{3}{128}x^4 - \ldots \quad (|x| < 1)$$

$$\frac{1}{\sqrt{(1+x)^3}} = (1+x)^{-3/2} = 1 - \frac{3}{2}x + \frac{15}{8}x^2 - \frac{35}{16}x^3 + \frac{315}{128}x^4 - \ldots \quad (|x| < 1)$$

with corresponding formulæ for $\sqrt{1-x}$, etc., obtained by reversing the signs of the odd powers of x. Also, provided $|b| < |a|$:

$$(a+b)^n = a^n \left(1 + \frac{b}{a}\right)^n = a^n + (n)_1 a^{n-1} b + (n)_2 a^{n-2} b^2 + (n)_3 a^{n-3} b^3 + \ldots$$

where $(n)_1$, $(n)_2$, etc., have the values given above.

Arithmetical Progression. In an arithmetical progression, a; $a + d$; $a + 2d$; $a + 3d$; . . ., each term is obtained from the preceding term by adding a constant, called the constant difference, d. If n is the number of terms, the last term is $l = a + (n-1)d$; the "average" term is $\frac{1}{2}(a + l)$;

fittings of the flanged design and also to limit the maximum size of the bronze and malleable valves and fittings to about $1\frac{1}{2}$ in. in size.

The fuel-oil service piping installed in the discharge of the fuel-oil service pump should be extra-heavyweight black steel pipe with all valves, flanges, and fittings of a heavyweight forged or cast-steel design. All take-down joints should be flanged along with all valves and fittings $1\frac{1}{2}$ in. in size and larger. All small sizes of valves and fittings are either of screwed or socket-welded design with the screwed design of valve seal-welded.

The fuel-oil suction piping material installed on all new U.S. Navy construction employs thin-wall steel tubing with all valves, flanges, and fittings either forged or cast steel. All joints are either welded or flanged, and no

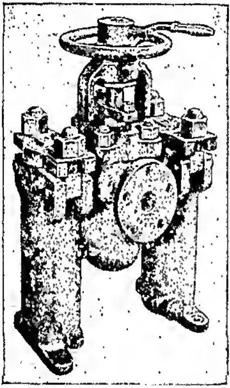

FIG. 11.—Plug-type duplex strainer for fuel oil. (*Courtesy of Elliott Company.*)

screwed joints are permitted. The oil service discharge piping material is the same except heavier weight tubing, flanges, valves, and fittings are required.

Strainers. The strainers installed in a fuel-oil service system should be of the duplex design so that the flow of oil will not be interrupted when cleaning of a strainer basket is required. This is most important since the interrupting of the flow of oil to the burners of a boiler in a steam-propelled vessel may result in a furnace explosion.

The basic design of a fuel-oil duplex strainer is the same as for a lubricating-oil duplex strainer, of which a detailed description is given on p. 1308. The outline and cross-sectional drawings (Figs. 11 and 12) show a typical plug-cock design of strainer, which is the most common in use for fuel-oil service systems.

The material of the bodies of the duplex strainers are cast steel, but in the case of the suction strainer cast iron may be used if the merchant vessel is not

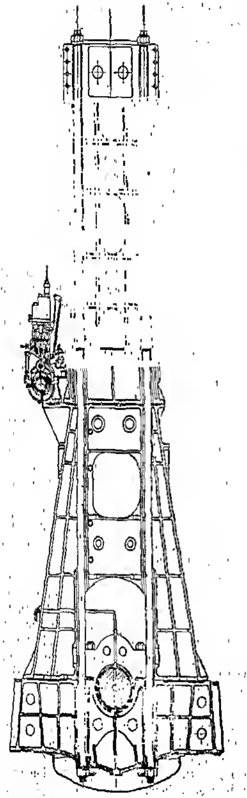

FIG. 7a.—M.A.N. two-cycle double-acting engine.

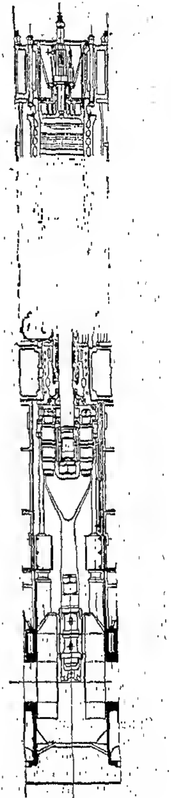

FIG. 7b.—M.A.N. two-cycle double-acting engine.

designed to the rules set forth in *Senate Report* 184. The valve or plugs are generally bronze or stainless steel. The strainer baskets are usually monel with $\frac{1}{16}$ in. diameter perforations for the suction strainers and $\frac{3}{8}$ in. diameter perforations with No. 30 wire cloth for the discharge strainer. The free

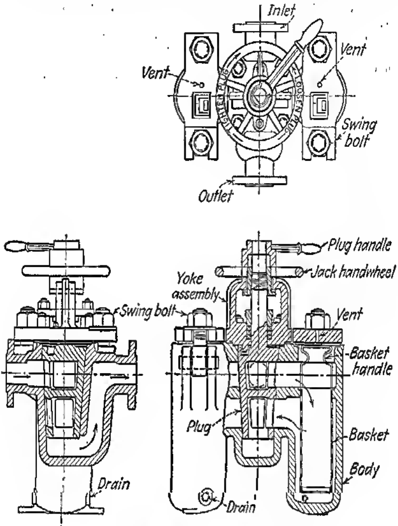

FIG. 12.—Fuel-oil strainer—duplex plug-cock type.

hole area through the strainer basket should be at least six times the area of the inlet pipe connection with the velocity of the liquid in the pipe not exceeding approximately 1.5 fps for a suction strainer and 4 fps for a discharge strainer.

part of the piston except in the case of crankcase scavenging engines, which will be explained in a later section.

Double-acting Engine. Just as in the case of the steam engine, in which the cylinder is closed at both ends and steam is admitted to first one side of the piston and then the other, it has been found possible to close both ends of the diesel cylinder and utilize both sides of the piston to produce power strokes. The conditions of operation are, however, more difficult because the piston rod must operate in a cylinder filled with gas that attains a temperature of more than 3000 deg and must pass through a stuffing box that will prevent leakage of gas at 500 to 700 lb pressure.

The necessity for this stuffing box and the fact that the presence of the piston rod interferes with the distribution of fuel in the lower combustion chamber and requires the use of two or more injection valves in the lower head, add complication to the head. Despite these difficulties the double-acting engine has proved highly successful and is widely used for large power installations.

The first successful double-acting engines operated on the four-cycle principle, but the necessity for air inlet and exhaust valves in both ends of the cylinder, with the accompanying complicated valve gear, made this type of engine very cumbersome and it was eventually abandoned in favor of the much simpler two-cycle design.

The cylinder of the two-cycle double-acting engine, as shown in Fig. 7, is essentially two single-acting cylinders placed end to end. There are two sets of scavenging and exhaust ports in the middle of the cylinder, one set of which is uncovered by the piston on its downward stroke, the other being uncovered on the up stroke. The piston is likewise, in its essentials, two single-acting pistons joined to form one long piston which is attached to a piston rod. The cyclic processes in the cylinder are the same as those described for the single-acting engine, but they occur alternately in the opposite ends of the cylinder so that the piston receives a power impulse on every stroke.

The absence of valves other than the injection valves makes the two-cycle double-acting engine comparatively simple. The starting air valve which is essential for starting the engine is generally used only in the upper cylinder head for the sake of simplicity. The double-acting engine is essentially a high engine, and in general its use in marine service is confined to power plants in which a high concentration of power per unit is desired. At one time it appeared that the double-acting two-cycle engine would entirely displace the single-acting type for powering large ships, but the development of better methods of scavenging, multiple-effect gear drives, and supercharging has enabled the single-acting engine to give it strong competition. At present its use is confined to large ships with the exception of a special design of double-acting two-cycle engine that finds considerable application in submarine service.

Opposed-piston Engine. A development that arose from the desire to obtain more power from a single cylinder than is possible by the use of the single-acting principle is that of the opposed-piston engine. As may be seen from the schematic diagram in Fig. 8, the cylinder of this type of engine is simply a cylindrical trunk, open at both ends, in which there are two pistons. The lower piston is connected to the crankpin in the conventional way through the medium of a piston rod, crosshead, and connecting rod. The upper

INTERNAL-COMBUSTION ENGINES

BY

LOUIS R. FORD

GENERAL

Diesel engine is a term commonly used to designate any engine in which atmospheric air is compressed to a pressure that will produce a temperature high enough to ignite the fuel that is discharged into the cylinder at the end of the compression stroke. The resulting combustion of the fuel produces a highly heated gas, the expansive force of which is utilized to perform work.

This definition is not strictly accurate, since the designation diesel was originally intended to apply to a type of engine invented by Rudolf Diesel to utilize a special thermal cycle conceived by him. Subsequent development of this engine resulted in modifications of the processes executed within it that involved variations of the cycle. In time the name became associated more with the kind of fuel used than with the cycle involved. As a result, in present-day practice the terms oil engine and diesel engine are practically synonymous although, as will be explained later, an oil engine is not necessarily a diesel engine.

METHOD OF OPERATION

In the usual diesel engine the cylinder is charged with atmospheric air while the piston is at the bottom of its stroke, and this air is compressed to a pressure of approximately 500 lb by the piston on its return stroke, this compression raising the temperature of the air to about 1000 F. At the end of the compression stroke, fuel oil in a highly atomized state is injected into this air and is ignited by its high temperature. The resultant burning of the oil raises the temperature of the gases produced to about 3000 F and increases the pressure accordingly. The piston in the meantime is moving downward on its power stroke under the influence of this pressure, and theoretically the resulting increase in volume occurs without rise in pressure of the gases during the combustion period. After combustion is completed, expansion of the gas behind the moving piston continues with a constantly decreasing pressure until the piston nears the end of its stroke, when an outlet from the cylinder is opened and the gases escape to the atmosphere. The cylinder is again charged with air and the cycle of operation repeated. An engine operating on the diesel cycle may, however, use fuel other than oil but no other fuel is used in marine service.

HEAT CYCLES USED IN OIL ENGINES

There are three thermal cycles that have a direct relation to oil-engine operation: the Otto cycle, the diesel cycle, and the dual cycle. In each of these there are five phases: (1) the cylinder is charged with air, (2) the air is compressed, (3) the fuel is injected and burned, (4) the resulting gas is expanded, (5) the burned gas is exhausted from the cylinder.

Otto Cycle. The Otto cycle, so named after the engineer who devised this system of operation, consists of five phases as follows: first, the cylinder is charged with air, then the air is compressed, and at the end of compression

piston has its piston rod connected to a crossbeam which has a side rod attached to each of its outer ends. These side rods are connected to two cranks, one on each side of the crank to which the lower piston is attached, through the medium of crossheads and connecting rods. Near the bottom end of the cylinder is a row of scavenging ports, and in a corresponding location at the top of the cylinder is a row of exhaust ports.

The action of the engine is as follows: Starting with the cylinder charged with air and both pistons at the outer ends of their strokes, *i.e.*, at opposite ends of the cylinder, the two pistons move inward and the air in the cylinder is compressed between them. At their point of nearest approach in the middle of the cylinder, compression is complete and fuel is injected into the combustion space between the two pistons. Pressure of the gas, produced by the resulting combustion, forces the pistons apart and they move out toward the ends of the cylinder, the lower piston pushing downward on its crank and the upper piston pulling upward on the two side cranks. As they approach the end of their travel, the upper piston uncovers the exhaust ports and shortly afterward the lower piston uncovers the scavenging ports. The scavenging air entering through the lower ports blows straight through the cylinder and out through the upper ports. This constitutes what is known as **uniflow scavenging.**

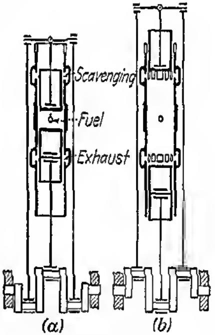

FIG. 8.—Schematic diagram of opposed-piston engine.

An apparent disadvantage of this type of construction is the fact that there are three cranks between two main bearings, which would seem to involve the possibility of crankshaft trouble. As a matter of fact, very little trouble has ever been experienced with such crankshafts and the opposed-piston engine is highly successful in service. Although a few small engines of this type have been built, this method of construction is usually associated in marine service with large, slow-speed engines. Since each cylinder of the engine is, in effect, two single-acting cylinders, it is readily seen that this construction enables a large amount of power to be concentrated in a short engine. The over-all height, however, is greater than that of the corresponding engine of the single-piston type.

A variation from the structural arrangement described in the foregoing is found in the opposed-piston engine using two crankshafts, one below the cylinders and one above. The lower piston is connected to the lower crankshaft, and the upper piston is connected in the same way to the upper crankshaft, the two shafts being connected by gears so that their rotation is synchronized. This arrangement eliminates the necessity for side rods and permits making the engine even shorter. The use of engines of this type is at present confined to submarine propulsion and auxiliary services, but they will undoubtedly be available for commercial service after the war.

the fuel is injected and burns during a period of time when the cylinder volume is unchanged, with the result that the pressure created by the heat of the gases is added to the pressure of compression. On the PV diagram, as shown in Fig. 1, the combustion line is vertical. At the end of the combustion period, expansion begins and the gases are expanded down to the point of release, after which the phase of exhaust occurs. As will be seen from the diagram, the use of this cycle involves combustion at constant volume. Accordingly, the pressure to which the air may be compressed in an oil engine is limited by the maximum allowable pressure in the engine cylinder and some external agency is required for igniting the fuel. This is the cycle on which the ordinary gasoline engine operates.

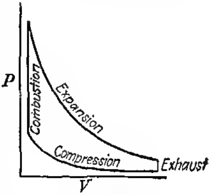

FIG. 1.—Otto cycle.

Diesel Cycle. The principal difference between the diesel cycle and the Otto cycle is, that, although the air-compression phase occurs in the former as in the latter, it is carried to a higher pressure and the fuel is injected at a graduated rate so that combustion occurs while the cylinder volume is increasing. Accordingly, the combustion pressure does not rise above the compression pressure and is represented on the diagram in Fig. 2 by a horizontal line. At the end of the combustion period, expansion occurs as in the Otto cycle and is followed by the exhaust phase at the end of the expansion phase. The combustion occurring in the manner described is known as **combustion at constant pressure.**

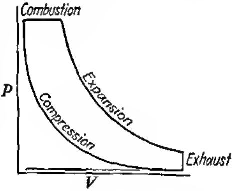

FIG. 2.—Diesel cycle.

An important difference between these two cycles lies in the way in which the combustion occurs. In the diesel cycle, the compression can be carried to any desired pressure, thereby increasing the temperature of the air enough to cause autoignition when the fuel is injected.

It should be noted that the theoretical diesel cycle, as described, differs somewhat from the practical cycle usually carried out in the actual diesel engine. This is shown in the diagrams in Fig. 3, which are indicator diagrams, taken from operating engines. Here it will be noted that the combustion line instead of being horizontal is curved upward. Although it is possible to adjust a diesel engine so that it will produce a combustion line that conforms closely to the shape of the theoretical diagram, it is found in practice that better efficiency is obtained if the combustion line has this upward-curving characteristic.

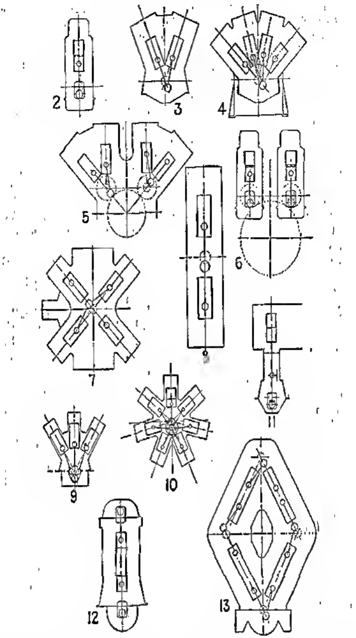

FIG. 9.—Special cylinder arrangements: 2, two-cycle cylinder with uniflow scavenging through valves in head; 3, V arrangement built in 6, 8, 12, and 16 cylinders; 4, porcupine type with two V's, producing a 32-cylinder unit; 5, double V with pinion between each pair of four-throw crankshafts; 6, quad unit of 24 cylinders; 7, pancake arrangement of four cylinders in same plane; 8, opposed cylinders produce a narrow unit; 9, W arrangement with two link rods on master connecting rod; 10, aircraft radial engine; 11, double-acting engine of well-known type; 12, two-crankshaft arrangement with opposed pistons; 13, diamond arrangement of four opposed piston engines.

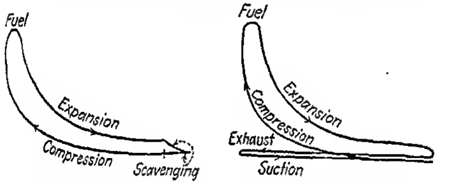
Dual Cycle. Further departure from the theoretical cycles is found in operating engines, especially those operating at high speed. The high-speed engine with smaller cylinders requires such a small fuel charge at each injection that graduated injection becomes very difficult. Also, certain inherent characteristics of combustion, which will be discussed later, make it practically impossible to burn the fuel at a rate corresponding to the increase of cylinder volume. As a result, we get a condition in the cylinder that is in effect a combination of Otto-cycle and diesel-cycle operation. The combustion line in this case will show a partial rise corresponding to combustion at constant volume, followed by a period of combustion at constant pressure. When this condition exists, the engine is said to be operating on a dual cycle. Practically all small high-speed diesels operate on this dual cycle.

Mechanical Cycles. The cycle discussed in the foregoing section are designated as thermal cycles and are not to be confused with mechanical cycles, of which there are two involved in diesel-engine operation. The thermal cycles represent heat processes, and such a cycle may be considered as a preliminary plan of engine operation. Mechanical cycles on the other



Two-cycle engine Four-cycle engine
FIG. 3.—Practical diesel cycle. Shapes of actual indicator cards.

hand are descriptive of the mechanical arrangements that are used for carrying out the heat cycles.

Two-stroke Cycle. In an engine operating on the two-stroke cycle, the cylinder is charged with air and the piston makes an upward stroke to compress the air. At the end of this compression period, fuel injection and combustion occur and the piston moves downward on its power stroke. When about 80 to 85 percent of the stroke has been completed, exhaust ports in the lower wall of the cylinder are uncovered or exhaust valves in the cylinder head are opened, depending on the construction of the engine, and the gases escape to the atmosphere, the pressure in the cylinder falling to atmospheric. Further movement of the piston uncovers scavenging ports in the side of the cylinder opposite the exhaust ports and air under a pressure of 1 to 5 lb blows into the cylinder, pushes out the remaining gases, and fills the cylinder with a fresh charge of air, after which the cycle is repeated.

It is thus seen that all the phases in the cycle of operations, namely, charging with air, injection and combustion of fuel, expansion, and exhaust occur during two strokes of the piston. From this we get the designation **two-stroke cycle.** In general practice this term is shortened to two-cycle and engines operating in this manner are known as two-cycle engines.

CYLINDER ARRANGEMENTS

Cylinders in Line. The conventional cylinder arrangement and the one most widely used is that in which all the cylinders are placed in line above the crankshaft and in a vertical position. Numerous combinations are found, including the 1-, 2-, 3-, 4-, 5-, 6-, 7-, 8-, 9-, 10-, 12-, and 16-cylinder combinations, but for marine propulsion it is not customary to use fewer than six cylinders for four-cycle and five for two-cycle engines, except in the case of opposed-piston engines or engines connected to the propeller shaft through reverse gears. Single-cylinder and two-cylinder engines are used only for auxiliary service, such as generator or pump drive.

V-type Engine. The trend toward greater concentration of power and more compactness of engines has found diesel designers taking a leaf from the book of designers of automotive and other types of gasoline engines as far as cylinder arrangement is concerned. A number of cylinder arrangements departing from the in-line practice have been developed, but the one most widely used is the V-type engine. Two lines of cylinders are placed in an inclined position diverging at the top and connected to a single crankshaft located at the point of intersection of the center lines. This arrangement permits the use of a very rigid type of frame and a high concentration of power within a given over-all space.

Originally designed for railway service, where limitations on space are severe, the V-type engine found ready acceptance in submarine service where the space limitations are still more severe. This type has also found wide application in certain classes of commercial marine service, particularly for electric drive.

Miscellaneous Arrangements. In the search for ways of concentrating power in a small space, several different cylinder arrangements have been designed. These are illustrated in the sketch in Fig. 9 which is self-explanatory. Aside from the V arrangement, the special arrangements shown have found very little use outside of naval service where they have been applied to the drive of special types of vessels, or in cases where some very special conditions call for a departure from conventional arrangements.

FUEL SYSTEMS

What may be considered the heart of the diesel engine is the fuel system, by means of which the fuel oil is delivered in metered quantities in an atomized state into the cylinders of the engine at the proper time. Starting at the bunkers or tanks in which the fuel oil is stored, the oil is pumped from there by a transfer pump and delivered to daily service tanks which are elevated above the engine. In most installations it is customary to interpose cleaning equipment between the supply pump and the service tanks, this cleaning equipment consisting of centrifuges or some type of filter. From the service tank, the fuel flows by gravity to the fuel-injection pumps, which perform the double function of metering the charge for each injection into the cylinders and forcing that charge into the cylinders.

At this point we find a difference in the early diesel engines and those of modern design. Originally all diesel engines utilized compressed air for injecting the fuel into the cylinders. Later development of mechanical or airless injection methods resulted in the abandonment of air injection in new marine installations. All marine diesel engines built today are equipped

Mention was made in a preceding paragraph of two methods of exhausting; one through ports in the cylinder wall and the other through valves in the cylinder head. In the former case, as may be seen in Fig. 4, the ports are near the bottom of the cylinder wall with the exhaust ports on one side and the scavenging ports on the other, the exhaust ports being higher than the scavenging ports. This latter arrangement is necessary in order that the exhaust ports will be uncovered and release the gases before the scavenging ports are opened. The scavenging ports are in communication with an air receiver, which is kept charged with air by means of a scavenging air pump either driven directly from the crankshaft of the engine or operated independently by means of an electric motor. The scavenging ports are shaped in such a way as to direct the entering air upward toward the top of the cylinder in order to clear the gases out of the upper end of the cylinder; in addition they are sometimes given an angular position so that the entering air will follow a helical path.

It will be seen that with this arrangement the exhaust ports must necessarily be uncovered before the scavenging ports, while the piston is making its downward stroke, and on the upward stroke the scavenging ports are covered by the piston before the exhaust ports have been covered, thus leaving the cylinder open to the exhaust receiver for a short period during the compression stroke, thereby permitting the entry of some burned gas. This condition is prevented in some two-stroke engines by the use of two rows of scavenging ports, one above the other, with automatic valves in the air receiver to close the upper row of ports or, in one design, both rows. On the down stroke of the piston the upper row of scavenging ports is uncovered before the exhaust ports, but the pressure of the gases in the cylinder holds the valves on their seats, and none of the gas can escape through the scavenging ports. As the piston proceeds downward and uncovers the exhaust ports and later the lower row of scavenging ports, exhaust and scavenging occur as previously described but, as soon as the pressure in the cylinder falls below the pressure in the air receiver, the automatic valves open and additional scavenging air enters through the upper row of ports. On the up stroke the piston closes the lower row of scavenging ports, but air continues to blow into the cylinder through the upper row and scavenging continues. When the moving piston covers the exhaust ports, the upper row of scavenging ports is still open and a slight supercharge is given to the cylinder, owing to the pressure of air in the air receiver. After further movement of the piston covers the upper row of scavenging ports, the cycle continues as before. A two-cycle engine with two rows of scavenging ports controlled by automatic valves is shown in Fig. 4.

In the crankcase scavenged engine the compressor is eliminated by using the undersides of the pistons to compress the air in the closed crankcase and providing passages from the crankcase to the scavenging ports.

Four-stroke Cycle. An engine operating on the four-stroke cycle requires air inlet and exhaust valves in the cylinder head. Starting with the piston at the bottom of the cylinder, the cylinder charged with air, and all valves closed, the operation is as follows: The piston moves upward on the compression stroke, at the end of which fuel is injected, combustion occurs, and the piston moves downward on the expansion stroke. Near the bottom of the stroke the exhaust valve in the cylinder head opens and, as the piston moves upward on its next stroke, the burned gases are pushed out of the cylinder. After the piston passes top dead center, the exhaust valve closes, the inlet

for mechanical fuel injection, but there are still many of the old, air-injection engines in service.

Air Injection. In this type of engine the fuel pump meters each charge of fuel and delivers it into the body of the injection valve located in the cylinder head. The body of this valve is also connected to a high-pressure air system so that it is at all times filled with air at about 900 lb pressure.

After the fuel charge is delivered into the valve, the valve gear operates to open the valve at the proper time in the cycle, and the high-pressure air in the valve blows the fuel violently into the cylinder. In the bottom of the valve body is an atomizer, usually consisting of some form of labyrinthine passage through which the oil is blown, thus causing it to be broken into fine particles and ejected from the valve body into the cylinder in the form of fog.

It would be perfectly feasible to operate the fuel-injection pump by an independent motor but, since its action must be accurately synchronized with the movements of the engine piston so that the fuel charge will be delivered at the proper time, it is obvious that the best method of operating it is through some sort of mechanism driven by the crankshaft of the engine. For this reason the fuel pump is always mounted on the engine where it can be operated by cams and gears driven from the shaft. The fuel pump may accordingly be considered a part of the engine itself.

Mechanical Injection. The mechanical injection of fuel as now used on all new marine engines differs from the earlier air injection principally by reason of the fact that no air is used in connection with the injection or atomization of the fuel. Instead, the fuel is forced into the cylinder by the fuel pump under high pressure and, by forcing it through minute orifices in the injection nozzle, this high pressure is converted into velocity, which causes the fuel to be blown into the cylinder in a fine mist similar to that produced by the air-injection valve.

There are two types of mechanical-injection systems in use. One is known as the common rail system and the other the jerk pump system, the latter being the more widely used. In the common rail system a supply pump delivers the fuel to a pressure pump, the discharge from which need have no definite time relation to engine rotation. This pressure pump maintains a pressure of 3,000 to 9,000 lb in a header or common rail, to which each of the injection valves is connected. The bodies of the injection valves—except some modified types—are filled at all times with this high-pressure oil and, when the valve-operating gear causes a valve to open, the oil is projected into the cylinder. The amount of fuel thus introduced into the cylinder depends upon the length of time the valve is held open. Provision is made in the valve-operating gear for regulating this duration of opening.

In the jerk pump system each fuel pump is connected directly to its corresponding injection valve or built into it. Although the line between the pump and the valve is at all times filled with oil, it is not under pressure except during the period when injection occurs. The fuel pump is of the constant-stroke type, and the same amount of oil is drawn into the pump barrel on each successive stroke. As soon as the plunger starts its discharge stroke, oil is forced out of the other end of the pipe connecting to the injection valve.

The injection valve is simply an accurately made spring-loaded check valve held on its seat by the tension of its spring. When the pressure, owing to the oil's being forced into the valve by the pump, is high enough to overcome the tension of the spring, the valve lifts and oil is forced through fine

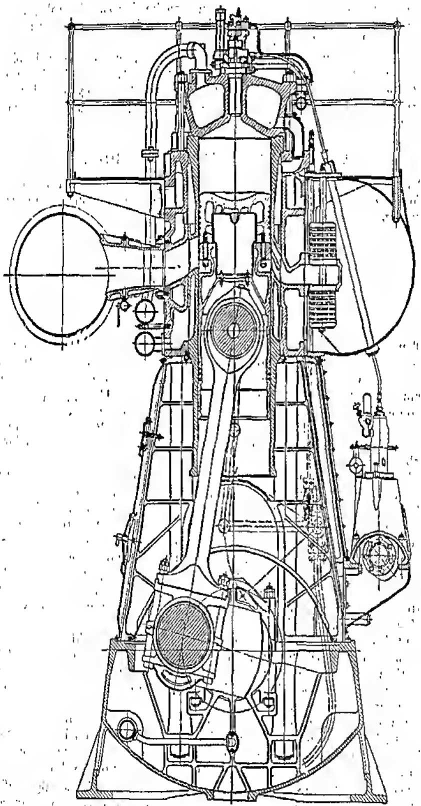


FIG. 4.—Nordberg two-cycle trunk-piston engine.

orifices in the injection valve oozzle and is projected into the combustion space in the form of a mist.

The amout of fuel that is thus forced into the cylinder must, of course, be varied to suit operating conditions. This variation is obtained by establishing, at a variable and controllable point in the stroke, a connection between the pump barrel and the suction line. This is done either by a spill valve operated by a linkage attached to the plunger or by a helical groove in the plunger in connection with a port in the plunger barrel. In this latter case, when the edge of this groove io the plunger uncovers the port, the pressure in the pump barrel is released. The helical shape of the groove makes it possible to vary this time of uncovering the port by rotating the plunger by means of a control mechanism leadiog to the control station.

A separate pump is provided for each cylinder on the engine, and all the pumps may be assembled in a single pump unit having a common suction tank, or each pump may be an independent unit mounted on the engine adjacent to the cylinder that it serves. The pump plungers are in all cases operated by cams upon a camshaft which is driven by gearing from the crankshaft of the engine.

COOLING SYSTEMS

During the process of combustion of fuel in the cylinder of the diesel engine the momentary temperature of the resultant gas reaches a point higher than the melting point of the metal of the cylinder. Some of the metal surfaces enclosing this high-temperature gas have relative motion and rubbing contact and must, therefore, be lubricated. Cooling of the engine cylinders is accordingly necessary, not only to keep the temperature of the metal below the melting point but also to keep the temperature low enough to permit maintaining a film of lubricating oil on the rubbing surfaces.

Water is the universally used cooling medium. Provision of an adequate and properly arranged path for the cooling water through the engine is a functioo of the engine designer, but it is of equal importance that pumps of the right type and capacity be selected and the associated piping be correctly arranged when the engine is installed io a ship.

In the early days of marioe diesel engineering it was the universal practice to use the flotation water for cooling, because of its ready availability and the simplicity of its application. All that was required was a pump to draw in water through a sea suction, force it through the cooling system, and discharge it overboard. Later, improved engineering practice eliminated the use of flotation water, but on some of the older vessels it is still used. Also for operation in localities such as the Great Lakes, where the water is fresh and soft, this is common practice.

There are three things that make it inadvisable to use water drawn from overboard for cooling: First, sea water, eveo when it is perfectly clean, contains dissolved magnesium, sodium, and lime which settle out in the form of hard scale if the temperature of the water rises beyond a certain point. This scale forms on the surfaces of the cylioder jackets and seriously interferes with the necessary transmission of heat.

Second, in harbors where the water is shallow and usually contaminated with sewage the bad effect of salt water is added to by the heavy silt content of the water, causing the jackets to fill up with mud unless cleaned frequently. In fresh-water rivers the scale-forming salts may be absent, but the silt content is usually very high and mud formatioo in the jackets is rapid.

valve opens and, as the piston continues on its downward stroke, a fresh charge of air is drawn into the cylinder. Near the bottom dead center the inlet valve closes and the cycle begins again.

It is thus seen that for the execution of this cycle, four strokes of the piston are required, hence the designation **four-stroke cycle.** As in the case of the two-cycle engine, this term is usually shortened to four-cycle, and engines operating in this manner are designated as four-cycle engines. A typical four-cycle engine is shown in Fig. 5.

CLASSIFICATION OF DIESEL ENGINES

All diesel engines fall into one of two type classifications, either two-cycle or four-cycle, but a further subdivision according to structural arrangement may be made as follows:

$$\text{2-cycle}\left\{\begin{array}{l}\text{Trunk-piston type}\\ \text{Crosshead type}\\ \text{Single-acting type}\\ \text{Double-acting type}\end{array}\right\}\text{—4-cycle}$$

Opposed-piston type—2-cycle only

Trunk-piston Engine. This type, examples of which are shown in Figs. 4 and 5, gets its name from the fact that the piston is made in the form of a cylindrical trunk, closed at the upper end and open at the lower, and having a length equal to about twice the diameter. The upper part of the piston contains the rings, and the walls are of thickened section to enable it to carry the pressure load and transmit heat rapidly. Below the head is an extension or skirt, which may or may not be made as a separate piece bolted to the head.

About midway of the piston are cast bosses, bored to receive a piston pin for attaching the piston to the connecting rod, which serves as the connecting link between the piston and the crankshaft and converts the reciprocating motion of the piston into rotary motion at the shaft. An alternate method of attaching the connecting rod to the piston utilizes a separate piston-pin carrier which is bolted inside the piston at its upper end. Another method is to attach the piston pin directly to flanges inside the piston by long studs which pass through the flat ends of the pin. These alternate methods eliminate the heavy bosses and the holes through the sides of the piston and permit making it a symmetrical, unbroken cylindrical casting.

In this trunk-piston form of construction the piston, in addition to forming a closure for the cylinder, serves in lieu of a crosshead for transmitting the side thrust of the connection rod. In the two-cycle engine the piston skirt also serves to cover the exhaust and scavenging ports when the piston is in the upper part of its stroke.

Another feature of the trunk-piston engine is that the lower end of the cylinder is open to the crankcase, and means must be provided for preventing oil vapor from the crankcase being drawn up into the cylinder. This generally takes the form of scraper rings in the lower end of the skirt.

Crosshead Engine. A type of construction that is generally confined to large engines is shown in Fig. 6. Here it may be seen that the connection between the piston and the crankshaft is through the medium of a piston rod, a crosshead, and a connecting rod. The piston rod, to which the upper end

The third troublesome factor is the highly corrosive action of harbor waters containing sewage and by-products from manufacturing plants. Fresh river water may also be corrosive, owing to the character of the land through which it flows.

Closed-system Cooling. The foregoing considerations led to the universal adoption of the closed-system method of cooling, except in such localities as the Great Lakes, previously mentioned. In this type of system fresh, soft water is circulated through the engine jackets, then passed through a cooler, and returned to the pump for recirculation. The fresh water is used over and over, and the only use made of flotation water is to pass it through the heat exchanger for cooling the jacket water.

Engine System. The cooling system may best be considered in two divisions: that part of it forming a part of the engine structure, and the part forming the circulatory system exterior to the engine. The focal point of the system lies in the metal surrounding the combustion space, where the most rapid transfer of heat must occur. The amount of heat transferred at this point and the rate of heat flow required are the factors that determine the pump capacity and arrangement of the circulatory system.

The usual arrangement found on the engine calls for a fore-and-aft header located near the lower ends of the cylinders, with a branch connecting to each cylinder jacket near its bottom end. Water flowing into each jacket rises to the top and passes into the cooling space in the cylinder head, either through holes in the top of the jacket that register with corresponding holes in the head, or through external jumper pipes connecting the jacket and the head. Since the area around the fuel-injection valve requires intensive cooling and in many engine designs is the most obstructed part of the head, it is customary to arrange nozzles or baffles in the head to direct and accelerate the flow of water around the fuel-valve housing or provide a separate water line to the fuel-valve jackets.

In the case of larger engines in which the exhaust valves must be cooled, a connection from the cylinder head allows the water to flow from the cylinder-head jacket into a jacket built into the exhaust-valve cage, from where it leaves through an outlet pipe that usually connects with a jacket surrounding the exhaust manifold. From the exhaust manifold it leads back to the systems or is discharged overboard, depending on whether the closed or open system is used. It should be noted that in some cases the exhaust manifold is not provided with a water jacket, in which case the connection to the exhaust manifold is omitted. In smaller engines that do not require cooling of the exhaust valves the discharge from the cylinder usually goes direct to the exhaust manifold or to the system, as the case may be. If the air compressor is attached to the engine, a branch from the main water manifold supplies water to the jackets on the compressor. Likewise, in the case of exhaust turbo-charged engines, the jacket of the exhaust turbine is connected to the cooling system.

Piston Cooling. Although the piston-cooling arrangements of modern engines do not form a part of the water circulation system, it is in order to mention it here because it is a part of the engine-cooling system. In smaller engines except those of high output the heat absorbed by the piston from the gases in the cylinder is conducted to the cylinder walls and is carried away by the jacket-cooling water, but in most engines having pistons of approximately 15 in. or more in diameter, the heat transfer by this method is not rapid enough to prevent overheating of pistons, and a direct means of cooling

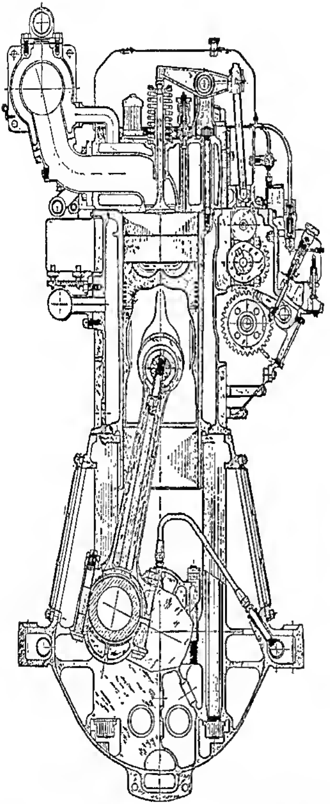

Fig. 5.—Cooper-Bessemer four-cycle trunk-piston engine.

the pistons must be provided. It should be noted, however, that there are some engines operating with uncooled pistons as much as 18 in. in diameter. In the early diesel engines water was used for piston cooling, but this practice has been abandoned in favor of the use of oil as the cooling medium. The most convenient source of oil for this purpose is the lubricating system, and in all except very large engines the oil for cooling the pistons is taken from this system. The manner in which it is done will be explained in connection with the discussion of lubrication. In very large engines it is customary to make the piston-cooling system entirely separate from the lubricating system, with its own pumps and circulatory system.

Circulatory System. In closed-system cooling the circulatory system consists of a fresh-water storage tank, a circulating pump which draws the water from this tank and discharges it to the engine, a heat exchanger through which the water is passed before reaching the engine, and a raw-water pump which pumps flotation water through the heat exchanger for cooling the fresh water. The course of the cooling water is from the storage tank into the circulating pump, thence through the heat exchanger to the engine jackets, then back to the storage tank. In installations where the total amount of water in the system is large, the storage tank may be eliminated and the water returning from the engine jackets may go directly to the pump. An elevated expansion tank located at any convenient point above the engine serves to ensure the system's being filled with water at all times.

It is common practice to insert a lubricating-oil cooler in the raw-water circuit so that the same water that cools the fresh jacket water may be used to cool the lubricating oil. There are heat exchangers available that combine the lubricating-oil cooler and water cooler in a single shell with suitable connections.

Of late years there has been a growing tendency to connect to engines of smaller sizes all the auxiliaries that are needed to keep it in operation, so that when the vessel is under way it will not be necessary to operate independent auxiliaries. In this case the circulating pumps for fresh water and raw water are driven from the crankshaft of the engine, and in the cases of small engines the heat exchanger may be mounted on the engine frame. In most cases it is customary to use centrifugal pumps for circulating the water; when they are attached to the engine, a type is used that will operate in either direction so that reversal of the engine does not interfere with the flow of water. When attached pumps are used, an independently driven unit can be used to circulate jacket water before starting and after stopping the engine. This is known as a "before-and-after pump," and its principal value is in preventing overheating of the engine after it is stopped. This pump is often combined with a lubricating-oil circulating pump, in a single unit.

The heat exchangers used for cooling the water are usually of the tubular type, but there are several different designs of tube arrangements. A commonly used one is made up of a nest of small tubes expanded in headers and inserted into a cylindrical shell. The raw water passes through the tubes, and the water to be cooled fills the shell and surrounds the exterior of the tubes, with baffles arranged in the shell to cause the water to flow back and forth across the tubes. Another type of heat exchanger used on small engines utilizes a flat type of tube, but the cooling action is the same.

Cooling-water Requirements. The amount of cooling water required and hence the capacity of the pumping equipment are governed by the amount of heat to be transferred from the burning fuel in the cylinder to the

of the piston is attached, is fastened at its lower end to the crosshead, which is supported in guides bolted to the engine frame. In an alternate design the piston rod is omitted, and the crosshead is attached directly to the bottom of the piston. A crosshead pin serves to connect the top end of the connecting rod to the crosshead, the bottom end being attached to the crankpin.

Since with this arrangement all of *the side thrust of the connecting rod is* transmitted by the crosshead, the piston is subjected only to the vertical thrust due to gas pressure, and there is no need for the long piston skirt in so far as side thrust is concerned. It is needed, however, in the two-cycle engine to cover the exhaust and scavenging ports. The absence of ports in the four-cycle cylinder makes the skirt unnecessary with crosshead construction and such engines are characterized by a short piston in the form of a closed cylindrical box, bolted to the top end of the piston rod.

Use of the crosshead construction with a piston rod permits the cylinder to be isolated from the crankcase by means of a horizontal diaphragm, the piston rod operating through a packed stuffing box in the diaphrogm.

It may be seen that the introduction of a crosshead and piston rod increases the height of the engine and, where headroom is a factor, trunk-piston construction is to be preferred. In the small and medium sizes, the trunk-piston engine has a lighter specific weight and is cheaper to build. For large engines the crosshead construction is preferable because the piston is simpler, the cylinder may be isolated from the crankcase, and the rate of cylinder liner wear is generally less. Consequently the two types of construction are generally identified, respectively, with the small and medium-sized engines in one case and large engines in the other.

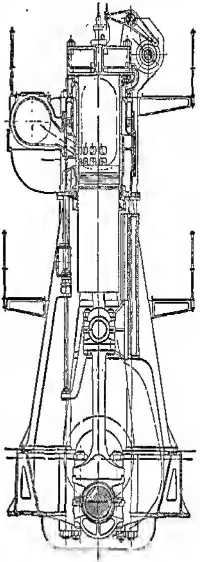

FIG. 6.—H.O.R. crosshead-type engine.

Single-acting Engine. In the engines thus far shown, all the processes involved in the thermal cycles used are carried out on one side of the piston. Consequently, the piston receives a power impulse only once in every two strokes in the two-cycle and once in every four strokes in the four-cycle. All such engines are designated single-acting engines, and the vast majority of diesel engines thus far built are of this type. No use is made of the lower

water in the jackets. It has been found that, in the average engine, 25 to 30 percent of the total heat in the fuel will be transferred to the cooling water, and for purposes of estimating capacity requirements the higher figure is customarily used. When using a fuel with a heat value of 18,500 Btu at the rate of 0.4 lb per hp per hr, the amount of heat to be carried away by the cooling water will be 18,500 × 0.4 × 0.30 = 2,220 Btu/(hp)(hr).

The controlling factor in determining the amount of water that must be circulated in order to carry away this heat is the temperature rise desired. It is inadvisable to have too great a difference between the temperature of the water entering the jackets and that of the water leaving the jackets, as this sets up severe temperature stresses in the metal of the cylinder liner. This temperature difference should not be more than 15 to 25 deg with an outlet temperature of between 120 and 160 deg. As a general rule it is conducive to engine efficiency to operate with an outlet temperature as high as is consistent with maintaining cylinder lubrication. Where the high outlet temperature is used, it may be necessary to regulate the temperature of the inlet water if the temperature difference is to be kept right. In general it is better to maintain a large volume of flow with the inlet at a high temperature than to use a small flow of very cold water.

The amount of water in gallons per minute required for cooling the engine may be determined by the following formula:

$$gpm = \frac{hhv \times W \times h \times P}{(t_2 - t_1) \times 500}$$

where hhv = heat content of fuel per lb
W = lb fuel used per hp per hr
h = percent of heat absorbed by cooling water
P = bhp
t_1 = temperature of inlet water
t_2 = temperature of outlet water

Example. Take an engine of 800 bhp, which uses 0.4 lb fuel per hp per hr, the heat content of the fuel being 18,500 Btu. If a temperature rise of 25 deg is desired, which will be $(t_1 - t_2)$, then the gallons per minute will be

$$\frac{18{,}500 \times 0.4 \times 0.30 \times 800}{25 \times 500} = 242 \text{ gpm}$$

The foregoing formula may or may not agree with the engine manufacturer's recommendation. In such cases, the latter should be followed.

Pump Capacity. It is general practice to provide circulating pump capacity considerably in excess of the amount required for cooling as designated by calculations such as this, but there is no universally accepted rule followed in this connection. Investigation by the author of a number of ships in service equipped with different makes of engines showed that the circulating-water-pump capacities varied from 5 to 9 gal per hp per hr. There is a tendency in modern practice to use larger amounts of the order of 15 to 20 gal per hp per hr in order to maintain a small temperature drop.

Cooler Capacity. There will be found a similar variation in practice in regard to the capacity ratings of different makes of heat exchangers. In determining capacity, the amount of heat to be taken away by the water is

and the sum of the n terms is n times the average term, or $S = \frac{1}{2}n(a + l)$. The **arithmetical mean** between a and b is $(a + b)/2$.

Geometrical Progression. In a geometrical progression, a; ar; ar^2; ar^3; . . ., each term is obtained from the preceding term by multiplying by a constant, called the **constant ratio, r.** The nth term is ar^{n-1}. The sum of the first n terms is $S = a(r^n - 1)/(r - 1) = a(1 - r^n)/(1 - r)$. If r is a positive or negative fraction, that is, if $-1 < r < +1$, then r^n will approach zero as n increases, and the sum of n terms will approach $a/(1 - r)$ as a limit. The **geometric mean** between a and b is $\sqrt{ab}$; also called the **mean proportional** between a and b (p. 113; construction, p. 102).

The **harmonic mean** between a and b is $2ab/(a + b)$.

Summation of Certain Series by Second and Third Differences. Let $a_1, a_2, a_3, \ldots a_n$ be any series of n numbers, as in the first column of the adjoining scheme. By subtracting each number from the next following, form the column of "first differences," and by repeating this process, form the columns of second, third, etc., differences. If the kth differences are all equal, so that subsequent differences are all zero, the original series is called an arithmetical series of the kth order. In this special case the series can be summed as follows: Denote the numbers which stand at the head of the successive columns of differences by $D', D'', D''', \ldots$ Then the nth term of the series is a_n, and the sum of the first n terms is S_n, where

$$a_n = a_1 + (n - 1)D' + \frac{(n-1)(n-2)}{1 \times 2}D'' + \frac{(n-1)(n-2)(n-3)}{1 \times 2 \times 3}D''' + \ldots$$

$$S_n = na_1 + \frac{n(n-1)}{1 \times 2}D' + \frac{n(n-1)(n-2)}{1 \times 2 \times 3}D'' + \frac{n(n-1)(n-2)(n-3)}{1 \times 2 \times 3 \times 4}D''' + \ldots$$

If the series is, for example, of the third order, each of these formulæ will stop with the term involving D'''; and only a few terms of the series are required for the computation of the D's. (Differentials, p. 159.)

Sum of the Squares or Cubes of the First n Natural Numbers.

$$1 + 2 + 3 + \ldots + (n - 1) + n = \tfrac{1}{2}n(n + 1)$$
$$1^2 + 2^2 + 3^2 + \ldots + (n - 1)^2 + n^2 = \tfrac{1}{6}n(n + 1)(2n + 1)$$
$$1^3 + 2^3 + 3^3 + \ldots + (n - 1)^3 + n^3 = [\tfrac{1}{2}n(n + 1)]^2$$

Formula for Interpolation by Second Differences. In any ordinary table giving a quantity y as a function of a variable x, let it be required to find the value of y corresponding to a value of x which is not given directly in the table, but which lies between two tabulated values, as x_1 and x_2. If $x = x_1 + md$, where $d = x_2 - x_1$ = the constant interval between two successive x's, and m is some proper fraction, then the corresponding value of y will be given by the formula

$$y = y_1 + mD' + \frac{m(m-1)}{1 \times 2}D'' + \frac{m(m-1)(m-2)}{1 \times 2 \times 3}D''' + \ldots$$

where $D', D'', D''', \ldots$ are the first, second, third, . . . differences in the

series of y's which begins with y_1 (see above), provided the function is of such a nature that the differences of higher orders become negligibly small.

The coefficients of D', D'', D''', . . . in the formula are the binomial coefficients for fractional values of m (see following table). The several terms of the formula (with careful attention to sign) are the successive corrections which must be added to y_1; the sum of these corrections should be rounded out to the nearest unit of the last significant place before adding. If $D' < 4$, the term involving D'', and later terms, can be neglected; the formula then reduces to $y = y_1 + mD'$, which is the familiar formula for ordinary, or "linear," interpolation. If $D''' < 8$ (or $D'''' < 12$, or $D''''' < 16$), the term involving D''' (or D'''', or D''''') can be neglected.

Binomial Coefficients for Fractional Values of m

m	$(m)_2$	$(m)_3$	$(m)_4$	$(m)_5$
0.0	− 0.0000	0.0000	− 0.0000	0.0000
0.1	− 0.0450	0.0285	− 0.0207	0.0161
0.2	− 0.0800	0.0480	− 0.0336	0.0255
0.3	− 0.1050	0.0595	− 0.0402	0.0297
0.4	− 0.1200	0.0640	− 0.0416	0.0300
0.5	− 0.1250	0.0625	− 0.0391	0.0273
0.6	− 0.1200	0.0560	− 0.0336	0.0228
0.7	− 0.1050	0.0455	− 0.0262	0.0173
0.8	− 0.0800	0.0320	− 0.0176	0.0113
0.9	− 0.0450	0.0165	− 0.0087	0.0054

Here $(m)_2 = \dfrac{m(m-1)}{1 \times 2}$, $(m)_3 = \dfrac{m(m-1)(m-2)}{1 \times 2 \times 3}$, $(m)_4 = \dfrac{m(m-1)(m-2)(m-3)}{1 \times 2 \times 3 \times 4}$, etc. Compare p. 39.

Permutations. The number of possible permutations or arrangements of n different elements is $1 \times 2 \times 3 \times \ldots \times n = n!$ (read: "n factorial").

If among the n elements there are p equal ones of one sort, q equal ones of another sort, r equal ones of a third sort, etc., then the number of possible permutations is $(n!)/(p! \times q! \times r! \times \ldots)$, where $p + q + r + \ldots = n$.

Combinations. The number of possible combinations or groups of n elements taken r at a time (without repetition of any element within any one group), is $[n(n-1)(n-2)(n-3) \ldots (n-r+1)]/(r!) = (n)_r$. (See table of binomial coefficients, p. 39.) If repetitions are allowed, so that a group, for example, may contain as many as r equal elements, then the number of combinations of n elements taken r at a time is $(m)_r$, where $m = n + r - 1$. Note: $(n)_1 + (n)_2 + \ldots + (n)_n = 2^n - 1$.

SOLUTION OF EQUATIONS IN ONE UNKNOWN QUANTITY

Roots of an Equation. An equation containing a single variable x will in general be true for some values of x and false for other values. Any value of x for which the equation is true is called a **root** of the equation. To "solve" an equation means to find all its roots. Any root of an equation, when substituted therein for x, will "satisfy" the equation. An equation which is true for all values of x, like $(x+1)^2 = x^2 + 2x + 1$, is called an **identity** [often written $(x+1)^2 \equiv x^2 + 2x + 1$].

Types of Equations.

(a) Algebraic Equations:

of the first degree (linear), *e.g.*, $2x + 6 = 0$ (root: $x = -3$);
of the second degree (quadratic), *e.g.*, $x^2 - 2x - 3 = 0$ (roots: $-1, 3$);
of the third degree (cubic), *e.g.*, $x^3 - 6x^2 + 5x + 12 = 0$ (roots: $-1, 3, 4$).

usually assumed to be 3000 Btu/(hp)(hr), although this is higher than the amount actually dissipated. The rate at which the heat is transferred will vary with the velocity of water through the cooler. With a velocity of 7 to 5 fps, an average rate of heat transfer of 275 Btu/(sq ft)(hr)(deg of mean temperature difference) is obtained. The amount of raw water used will be an amount equal to or exceeding by three times the amount of water to be cooled when using higher temperature differentials such as 25 to 30 deg. A formula that has been developed for calculating the amount of surface required for the heat exchanger is as follows:

$$\text{Surface, sq ft} = \frac{Q}{t_m \times C \times F}$$

where Q = heat injection, Btu per hr

t_m = log mean temperature difference between raw water and jacket water

U = a factor representing over-all rate of heat transfer

F = a foulage factor, 100 percent for clean tubes to 85 percent for foul tubes

The amount of raw water required in gallons per minute will be

$$\text{Gpm} = \frac{Q}{(t_2 - t_1) \times 500}$$

where t_1 = inlet temperature of raw water

t_2 = outlet temperature of raw water

LUBRICATING SYSTEM

There is probably no other factor in diesel-engine operation that has been given more study by designers than lubrication. This has resulted in the development of a standard arrangement of the lubricating system. The action of the lubricating oil and the chemistry involved in the production of oils suitable for lubrication, under the special conditions that exist in diesel engines in different types of service, are still the subject of widespread study and experiment. The application of lubricant to the rubbing surfaces in the engine is accomplished through the medium of two separate systems: one for the cylinders and one for the bearings.

Cylinder-lubricating System. The lubrication of the cylinder liner surface upon which the piston rings must travel and which is repeatedly exposed to the flaming gas in the cylinder presents a special problem requiring a method of application that makes it necessary to use equipment for this purpose separate from the equipment used in the lubrication of the rest of the engine. The oil must be applied in very small quantities, at frequent intervals, and must be distributed around the circumference of the liner so that it can be spread over the entire surface by the piston rings during their travel.

The mechanism used consists of a number of small pumps assembled in groups of 2 to 24 in units known as mechanical lubricators. Each of these small pumps is connected by means of small-diameter tubing to a fitting on the outside of the cylinder that passes through the jacket and connects with a hole in the wall of the liner, the number of such fittings and the correspond-

reverse direction with air, the camshaft remains stationary until the lost motion in the coupling is taken up, thus changing the angular position of the cams relative to the crankshaft.

Gear Reversing. When small engines of about 200 hp or less are used for propulsion, the need for reversing mechanisms is eliminated by the use of reverse gears, by means of which the direction of propeller rotation is reversed without stopping the engine or changing its direction of rotation. This arrangement permits the use of electric starting and eliminates the air compressor and its associated tanks and piping.

The reverse-gear unit is placed between the crankshaft and propeller shaft and comprises two trains of gears and clutches operated by a single lever. One train has a crankshaft gear and a propeller-shaft gear, with one intermediate gear, thus causing the propeller shaft to turn in the same direction as the crankshaft. The other has two intermediate gears, thus giving the propeller shaft rotation opposite to that of the crankshaft. Movement of the control lever in one direction engages the clutch connected to one train, while movement in the opposite direction engages the other train. Placing the lever in mid-position disengages both clutches, and the engine continues to run while the propeller shaft remains stationary.

In another type of gear the gear train is used only in the reverse direction. When running ahead, the entire unit is locked together and acts as a solid connection between crankshaft and propeller shaft. For use in driving a propeller with a high-speed engine, the reverse gear is combined with a reduction gear, the combined unit forming an integral part of the engine structure.

SUPERCHARGING

The first marine application of supercharging, in the form of an electrically driven blower that discharged air into the intake manifolds of two engines, gave results that led to the development of present-day methods and greatly widened the field of the four-cycle engine. The basic purpose of supercharging is to get more air into the engine cylinder during each charging period than is possible by natural aspiration, in order that more fuel may be burned, a higher mep obtained, and more power produced with a cylinder of given dimensions. The procedure has now been developed to the point where supercharging equipment is an integral part of the design of some makes of engines and is optional with many others.

Three methods of supercharging have been developed commercially: (1) the use of the bottom ends of the cylinders as air compressors that discharge the air into a receiver cast around the cylinders; (2) the use of a rotary or displacement type of blower driven by gears or chains from the engine crankshaft; (3) the use of the exhaust gases from the engine to drive a turbine connected to a blower that discharges air into the inlet manifold of the engine.

This last is the most widely used and appears to be in a fair way toward acceptance as the universally standard method. It is possible, however, that experimental work now being carried on will develop some radically new concepts of supercharging. An advantage of the exhaust-turbo method is that it operates on free power that would otherwise be wasted, yet does not rob the exhaust gas of its heat and prevent its use in heat-recovery apparatus.

Effect of Supercharging. Since the pressure at the end of compression, with any given compression ratio, depends upon the pressure at the beginning of compression, it follows that if air at 4 to 6 lb pressure is forced into a

ing number of pumps required for each cylinder varying from four to eight. The mechanical lubricator assembly is arranged so that the pumps are all connected to a common suction chamber which is kept filled with oil.

All the pumps are operated by cams driven by a shaft connected through gearing to some moving part of the engine. The amount of oil discharged by each pump can be regulated, but the discharge is at the rate of only a few drops per minute. The lubricators are always situated below the cylinder they serve, and the tubing connecting them with the inlet fittings on the cylinder is always filled with a solid column of oil, so that each time a pump discharges a drop of oil into its tubing a corresponding drop is forced out of the other end into the cylinder. The rate of feed is a matter that must be determined by experience, but in general it will vary between 7 to 15 drops per minute from each pump. The number of points at which oil is discharged into the cylinder is also a matter to be determined by cut-and-try methods. In general, the objective sought is to have them spaced so that the oil spreading sideways on the cylinder wall from each feed will be able to meet the oil from the adjacent feeds.

Bearing Lubrication System. The bearings on all present-day diesel engines—except crankcase-scavenged types—are lubricated by means of a pressure system in which oil is continuously circulated and used over and over. The principal elements in the system as shown in Fig. 10 are a storage tank from which make-up oil is fed

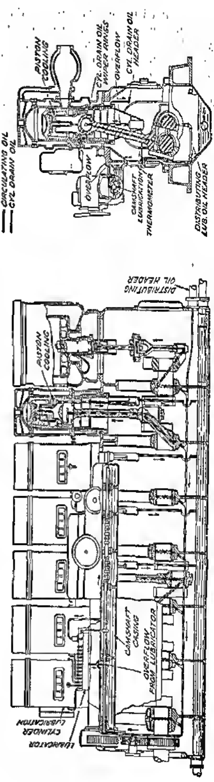

FIG. 10.—Typical lubricating system as used in Fairbanks-Morse engine.

cylinder that is designed for operation with atmospheric aspiration, the resulting compression pressure will be above normal. Consequently the supercharged engine may have a lower compression ratio than the unsupercharged engine and, if the supercharged engine is operated without the supercharger, the compression pressure will be below normal.

Reference to the diagram in Fig. 12, which shows an indicator card from a supercharged cylinder imposed on one from an unsupercharged cylinder, will show the effects obtained by supercharging. Since the greater weight of air in the cylinder permits the burning of more fuel, the combustion line will be higher; thus the mep will be greater although the maximum pressure will be the same, provided the compression ratio is properly adjusted. This means that the power obtained from the cylinder will be increased without any change in the dimensions of the engine. The practical application of this is to make possible the use of a smaller engine for a given propulsion power or provide more power for a given ship.

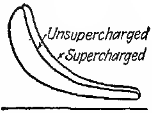

Fig. 12.—Indicator diagram showing effects of supercharging.

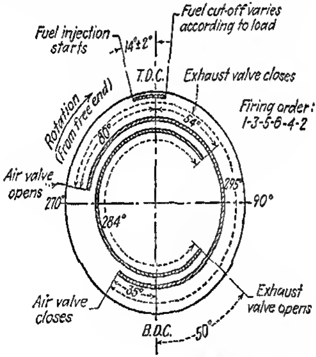

Fig. 13.—Valve diagram of Alco supercharged engine showing valve overlap.

The fact that more oil is burned in the cylinder does not, as might be expected, create a higher temperature in the cylinder or a higher temperature in the exhaust. Although more oil is burned, the ratio of oil to air is the same, owing to the presence of the additional air. Also the overlap of opening of inlet and exhaust valves allows air to blow through the combustion

into the system as required; a sump tank, which forms the reservoir from and to which the oil is circulated; a circulating pump, which forces the oil under pressure through the circulatory system on the engine; a heat exchanger for cooling the oil after it has passed through the engine; and some form of filter for cleaning the oil.

Circulation through the engine occurs as follows: The oil from the circulating pump is discharged into a fore-and-aft header which has a connection with each main bearing on the engine. These connections are sometimes made through the bearing cap and sometimes through the bottom half of the bearing, while the header may be a pipe or it may be a passage cored in the bedplate. The oil spreads out in the main bearings and, by way of a circumferential groove in each bearing that registers with a hole in the shaft, flows into the crankpin bearings. From the crankpin bearing it flows into a groove in the bearing shell, then flows upward through an axial passage in the connecting rod to the piston pin bearing. At each bearing some of the oil spreads out through the bearing, flows out of the end, and finally falls into the crankcase and thence to the sump.

Engines that require piston cooling have a connection between the crosshead or piston-pin bearing and the piston, arranged so that the oil flows from the piston-pin bearing up into the piston head, out through a connection in the piston, and thence into the crankcase.

There are a number of different forms of connections between the crosshead or wrist-pin bearings and the piston, but the function of all of them is the same. In some small engines the oil is jetted against the underside of the piston through a nozzle on top of the piston-pin bearing. The heat exchanger for cooling the oil is usually placed between the circulating pump and the distribution header on the engine, and is connected to the same raw-water pump that cools the jacket water. Current Navy practice, followed in some commercial installations, is to pass the jacket water through the oil-heat exchanger.

A necessary feature of an engine lubricated in this manner is a closed crankcase. With the oil being forced into the system under pressure and flowing out of each bearing, it is obvious that the rapidly moving cranks and connecting rods will dash the oil around violently and keep the crankcase filled with a heavy fog of oil. All openings in the crankcase must have oil-tight closures, otherwise there will be a serious loss of oil out of the system. As a matter of fact, the lack of tightness of the crankcase is a very common cause of loss of oil and resulting excessive oil consumption by the engine. It will also be evident that, since the cylinder of the trunk-piston type of engine is open to the crankcase at its lower end, there will be a large amount of oil thrown up onto the walls of the cylinder liner. This is the reason for the use of the scraper rings mentioned in connection with pistons.

The use of pressure lubrication has in modern engines been extended to include not only the principal bearings mentioned in the foregoing but also all the secondary bearings such as those for the camshaft. In many engines every moving part that requires lubrication is served by branches from the pressure system, and all hand oiling is eliminated.

Cleaning Lubricating Oil. The lubricating oil in its rapid passage through the engine is subjected to a number of deteriorating influences that cause the formation of carbon, gums, etc., in it. It also picks up any dirt or particles of metal that may be present in the engine. For this reason it is essential that a means be provided for cleaning the oil. There are two

space during the latter part of the exhaust period, thus scavenging the cylinder, cooling the piston and cylinder wall, cooling the gases, and taking away in the exhaust gases some of the heat that would otherwise be taken up by the cooling water. The manner in which the valve-timing overlap is produced is shown in the timing diagram of a supercharged four-cycle engine shown in Fig. 13.

The changes in operating conditions resulting from supercharging may be summed up as follows: The pressure at start of compression is higher, the compression pressure is the same, the mean pressure is higher, the exhaust pressure is higher, the temperature of combustion is the same, the mean temperature is higher, the exhaust gas temperature is lower, and less heat is carried away in the cooling water although the total heat is greater owing to higher hp output.

Exhaust Turbocharging. The elements in the exhaust turbocharging system are a gas-driven turbine, usually mounted on the engine, and a multiple-exhaust manifold for over three cylinders. The manifold must be arranged so that the exhaust valve of one cylinder is not opening when the inlet and exhaust valves of another cylinder are open.

A four-cylinder engine will require two pipes to the turbine arranged so that the cylinders on the same crank-phase angle are in one pipe. This would mean that, with the standard crank arrangement, cylinders 1 and 4 would have one pipe and numbers 2 and 3 the other pipe.

On six-cylinder engines with the standard arrangement of cranks, cylinders 1, 2, and 3 would have a common pipe and cylinders 4, 5, and 6 a common pipe.

An eight-cylinder engine with standard crank arrangements requires four pipes to the turbine. This is necessary because otherwise the scavenging effect of supercharging would be entirely lost. A centrifugal blower is mounted on the same shaft with the turbine and an air-inlet manifold connected to the discharge of the blower and to the air-inlet passage of the cylinder.

Multiple exhaust manifolds are used in order to take advantage of the fluctuating pressure of the gas, which varies from 2 to 7 lb. If all cylinders exhaust into a single manifold, the maximum and minimum pressures tend to neutralize each other, and a uniform pressure will exist in the manifold equal to or higher than that in the air-inlet manifold. With multiple manifolds the condition of fluctuating pressure can be maintained and the period of scavenging previously referred to, when the inlet and exhaust valves are both open, can be made to coincide with the time of lowest pressure in the exhaust passage. By this means positive scavenging and charging of the cylinder are obtained even though the average pressure of the gas in the exhaust manifold is about 5 lb and the pressure of the air in the inlet manifold may be as little as 4 lb. This will be understood by reference to Fig. 14.

It has been stated that the heat carried off by the cooling water is less in the supercharged engine. It should be noted that this applies only when sufficient overlap has been given to the exhaust and inlet valves to produce a pronounced scavenging effect. If an engine with normal valve setting is supercharged, it will be found that the heat carried off by the cooling water will increase directly with the horsepower, and the cooling water capacity must be increased accordingly.

At the present time about 500 hp seems to be the low limit on size of engine to which exhaust turbocharging can be economically applied. Engines below this size utilize built-in blowers driven by gears or chains, the blowers usually

general types of equipment used for this purpose: the centrifuge and the filter. At present there are only two types of centrifuge in use, and the principle on which they operate is the same. The dirty oil is run into a rapidly rotating bowl and, under the influence of centrifugal force, the foreign matter contained in the oil is separated and thrown outward against the walls of the bowl, and the clean oil flows out of the top of the bowl. This method of cleaning is very successful in removing all foreign matter held in suspension, but it will not remove collodial carbon or correct acidity (see p. 1310).

The other method of cleaning involves the use of filters, of which there are many different types, although the basic principle of all is the same. This involves forcing the oil through passages so minute that the suspended impurities cannot get through with the oil. These minute passages are provided by various types of material that are used for filtering. These include cotton waste, cloth bags, cellulose, and fuller's earth. Other types use metal or paper disks and other arrangements that are assembled in such a way as to provide minute passages between the disks for the flow of oil and the interception of foreign matter.

Various arrangements of the filtering equipment are used, and the methods of operation include batch cleaning and continuous by-pass cleaning. Theoretically, the best procedure would be to pass all of the oil through filters on its way to the engine, but this would involve filtering equipment of very great capacity. In the batch method of cleaning, all or a large part of the oil in the system is removed periodically for cleaning and replaced with new oil. After cleaning, the used oil is stored in the clean oil tank to be used as replacement oil. By this method the engine operates for a time with very clean oil, but as time goes on the oil gets progressively dirtier and may become extremely so before the next cleaning period.

The method most commonly used is continuously to by-pass a part of the oil through the filters and back to the system. Thus, the engine is always operating on a mixture of clean and dirty oil.

The amount of oil that must be circulated in the system is an indeterminate quantity, and there seems to be no generally accepted ratio of oil-pump capacity to engine power. Consequently wide variations in the quantity of oil circulated are found between different installations. As an example, it is found that in one 2,000-hp installation the oil-circulating pump has a capacity of 50 gpm, while in another installation of 950 hp a pump capacity of 91 gpm is provided. This is a situation that need not cause concern because it has little effect on design, layout, or operation of the plant. The oil in a forced-feed system circulates continuously in the system, regardless of what storage-tank capacity may be installed. Once filled, a system that holds 1,000 gal requires no more reserve storage capacity than one that holds 500 gal.

Lubricating-oil Consumption. The amount of oil circulated has little relation to oil consumed by the engine. Theoretically the only lubricating oil required by the engine should be that fed into the cylinders, and the oil circulated in the bearing lubrication system should last indefinitely. Actually there is some oil lost out of the system by being drawn up into the cylinders and burned, and considerably more is lost by leakage. In some designs this leakage is prevented by maintaining slightly less than atmospheric pressure in the crankcase.

Oil consumption of the engine is the amount used for cylinder lubrication, plus the amount of bearing oil burned or lost by leakage. It may be expressed

being of the Roots type, preferably with helical vanes. Development work is being done with small turbochargers, and it is expected that in the future it will be possible to apply them to much smaller engines.

An arrangement that is used in some recently built large diesel tugs employs independent supercharging blowers driven by electric motors. In order to prevent waste of power by the blower when the engine is operating at reduced

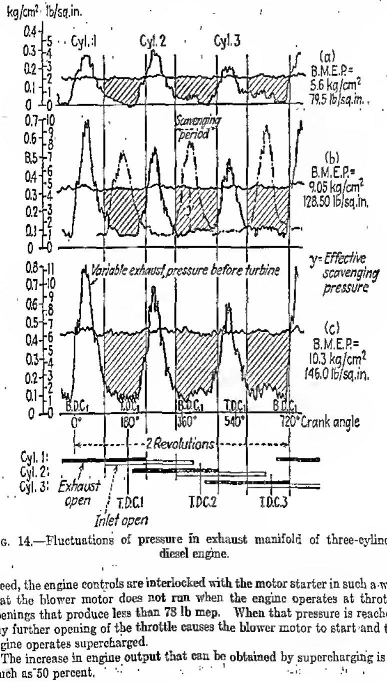

FIG. 14.—Fluctuations of pressure in exhaust manifold of three-cylinder diesel engine.

speed, the engine controls are interlocked with the motor starter in such a way that the blower motor does not run when the engine operates at throttle openings that produce less than 78 lb mep. When that pressure is reached, any further opening of the throttle causes the blower motor to start and the engine operates supercharged.

The increase in engine output that can be obtained by supercharging is as much as 50 percent.

in several ways, but the simplest and most easily visualized method is to state it in terms of rated horsepower-hours per gallon of oil. On this basis it will be found that the consumption will cover a wide range, from 1,500 to 10,000 hp-hr per gal. In general, the trunk-piston engine will use more than the crosshead engine, the high-speed engine will use more than the slow-speed engine, and the two-cycle engine will use more than the four-cycle engine. Aside from differences due to engine type, the condition of the engine and the quality of attendance will have a marked influence on consumption.

AIR SYSTEM

In addition to the air compression that is performed in the working cylinders of the engine and constitutes a phase in the diesel cycle, compression of air is required for the purpose of starting the engine, for the scavenging of the two-cycle engine and, in the case of the air-injection engine, for injecting fuel into the cylinders. Air systems may then be discussed under three divisions: injection system, scavenging system, and starting system.

Injection System. As explained previously, there are still a number of air-injection engines in service, and the air compressor constitutes a very important part of them. As pointed out, the fuel is injected into the cylinders of such an engine by air that must be at a pressure sufficiently high to project the fuel vigorously into a body of air in the combustion chamber that is compressed to about 500 lb. To do this the injection air must be compressed to about 900 to 1,200 lb.

Perfectly satisfactory operation can be obtained if the air compressor is independently driven, either by an electric motor or an auxiliary diesel engine, but by building the compressor into the engine and driving it from an extra crank on the engine shaft, operation is made much more convenient. In this case the compressor runs only when the engine runs and changes speed as the engine speed changes. Consequently it became standard practice to build the compressor into the engine and provide a separate independently driven compressor as a stand-by and for starting air. On some of the older ships an independent compressor was used to give the air its first stage of compression, the remaining stages being carried out by the attached compressor. The air may be taken from the engine room, from the outside, or from both. If all of it is taken from the engine room, the engine-room temperature may at times be reduced too much for the crew's comfort. Provision is frequently made to regulate the amount taken from either source by a butterfly valve in each intake pipe.

In order to reduce the amount of work required to compress the air, it is customary to carry out the compression in three stages and pass the air through coolers after each stage of compression. Pressures in the three stages are approximately in the ratio of 60: 240: 900 lb. The compressor is driven from a crank on the forward end of the crankshaft, and the piston is made as a single unit of three different diameters, with cylinder diameters to match. The cylinder bores are usually arranged so that the second-stage section is on the bottom, next to the crankcase. This prevents oil fog from the crankcase being drawn into the cylinder, as would be the case if the first stage were on the bottom, and also gives a better distribution of load.

Air from the first-stage cylinder passes from the discharge valves into an intercooler and, after being cooled, is drawn into the second-stage cylinder. After the second compression it is passed through a second intercooler and into the third-stage cylinder. After, this third compression it is passed

METHODS OF APPLICATION

Two general methods of application of the diesel engine to marine propulsion are in use: (1) direct drive, with one or more propellers driven by engines coupled directly to the propeller shafts, and (2) indirect drive, with one or more engines driving the propeller shaft through reduction gears or through the medium of electric motors supplied with current from generators driven by the engines.

A further variation in the methods of application is found in the number of screws used. In the early days of diesel propulsion, the use of twin screws was considered necessary in order to permit the use of propellers that could operate at the high speeds at which diesel engines were run and to provide a factor of safety by having power still available even if one engine should break down. Development of slower speed engines and improved propeller design in time eliminated the first condition and the demonstration of reliability in operation equal or superior to other types of propulsion machinery made multiple engines unnecessary from a safety standpoint.

In general it may be said that where weight and space are not controlling factors, direct drive is simpler and in most cases cheaper but, if space is limited and saving of weight is important, indirect drive is preferable.

Direct Drive. In considering direct-driven propellers there are several generalizations that apply. For the average vessel the rpm should be in inverse ratio to the horsepower, also the higher the speed for which a vessel is designed the higher the revolutions that can be used with a given power. Where for any reason a comparatively small propeller must be used, as on boats operating in shallow rivers or canals, the propeller speed will usually be near enough to the designed engine speed to call for direct drive.

With direct drive the usual arrangement is to locate the engine approximately amidship unless the type of service or the kind of cargo carried, such as in oil tankers, makes it more advantageous to place it in the extreme stern. Aft of the engine is a thrust bearing which prevents the linear thrust from the propeller from reaching the engine. In most large installations the thrust bearing is independent of the engine and mounted on a separate foundation, but in many of the smaller sizes it is attached to the bedplate and forms a part of the engine assembly. The length of intermediate shaft between the thrust bearing and the propeller shaft will of course vary with the location of the engine; in the case of tankers it disappears altogether, the propeller shaft being connected directly to the thrust bearing.

GEAR DRIVES

Although propulsion by direct drive has proved thoroughly satisfactory from the operating standpoint, there has been a distinct reversal of trend in regard to engine rotative speed and a growing acceptance of higher speed; but, in order to realize the advantages of reduced cost, weight, and space associated with the high-speed engine, indirect drive of the propeller must be resorted to. Two methods of indirect drive are in use: one utilizes reduction gears between the engine and the propeller shaft and the other uses the engine to drive a generator which supplies current to a propulsion motor on the propeller shaft.

Gear Arrangements. The main elements in a reduction gear are a large gear, known as a bull wheel, mounted on the propeller shaft; one or two

through an aftercooler and thence to the storage bottles and the injection valves.

The elements in the system are the compressor, the storage bottles, and the high-pressure piping leading to the injection valves. The capacity of the compressor is determined by the volume of the first-stage cylinder and is expressed in terms of cubic feet of free air per minute. In practice there is a wide variation among different builders in regard to capacity. It has been found that this variation in existing installations is from 0.2 to 0.35 *cu ft free air per min per bhp.*

The air bottles in which the air is stored are usually two in number and only one is used at a time, the other being shut off and kept in reserve. The one bottle that is in use serves as a surge tank to prevent fluctuations of pressure at the injection valves. The capacity of the air bottles should be based on the stroke volume of the engine cylinders. In practice, it is found that this capacity varies from fourteen times the stroke volume for small engines to one to two times the stroke volume for engines with cylinders 22 in. or more in diameter.

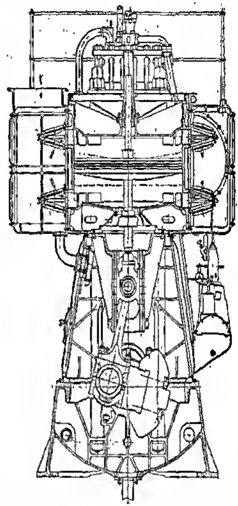

Fig. 11.—Engine-driven double-acting scavenging pump as used on Nordberg engine.

Scavenging Air System. As previously explained, the operation of the two-cycle engine requires the use of low-pressure air to blow the burned gases out of the cylinders. The compressor used to supply this air may be either a reciprocating pump or a rotary blower and is of light construction, owing to the fact that the pressure required is between 1 and 3 lb only. It should have a capacity sufficient to give a ratio of scavenging air volume to power cylinder volume of about 1.5 :1, and never more than 2: 1.

When the reciprocating type of scavenging pump is used, it is built into the engine, as shown in Fig. 11, is driven by an extra crank on the crankshaft, and is usually double-acting. The air is discharged into a receiver which in most cases consists of a fore-and-aft manifold bolted to the cylinders. In some cases a part of the engine frame or housing is closed in to form a receiver.

pinion gears, to which the engine or engines are connected; and the necessary bearings and lubrication equipment. These elements are assembled as a complete unit within its own casing. The ratio of reduction is usually about 1:2 and never exceeds 1:6. With a unit of this sort one, two, or four engines may be used. Three-engine operation is never resorted to except when one engine of a four-engine installation may be shut down temporarily.

For a one-engine installation the pinion may be in either the vertical or the horizontal plane passing through the center of the bull-wheel shaft. With the pinion in the vertical plane, the engine shaft must be at a height above the center line of the propeller shaft equal to the radius of the bull wheel, plus the radius of the pinion. It is obvious that this arrangement is suitable only for an engine of low over-all height. With the pinion in the horizontal plane, the engine may be placed low in the ship, but it will be displaced to one side of the centerline and its weight must be compensated for by placing auxiliary machinery on the other side.

Two-engine and four-engine installations permit symmetrical arrangement of engines and gears. Two pinions are used in each case, with one engine connected to each or two engines connected to each, according to whether two of four engines are used. In the two-engine installation the gear set may be located either aft or forward of the engines. In the latter case the propeller shaft leads aft between the two engines. This is an arrangement well suited to tankers or other bulk-cargo ships in which the engine room is located in the extreme stern. With the four-engine arrangement, the engines are located at the four corners of a rectangle with the gear set in the center. The schematic arrangement of a two-engine gear drive is shown in Fig. 15.

Gear Forms. A factor that contributed more than any other to the success of reduction gears was the development of methods for accurately cutting herringbone teeth. The helical form of tooth with the gradual engagement of each succeeding pair of teeth produces noiseless operation and also creates an axial thrust tending to jam the teeth together. In the double-helical or herringbone form the thrust acts in equal and opposite directions. Consequently most reduction gears are made with either continuous or interrupted herringbone teeth. In the former each tooth is in the form of a closed V, while in the latter the V is open at the point.

Although the thrust due to tooth action is thus automatically eliminated, provision must be made to prevent the thrust of the propeller from reaching the gears. To accomplish this a thrust bearing is mounted on the propeller shaft, and it is customary to build this thrust bearing into the gear set as a part of the complete unit.

In order to prevent any possibility of binding or unequal wear of the gear teeth, the pinion shaft is given a small amount of float so that the teeth can center themselves. In some cases a certain amount of flexibility is given to the pinion shaft by making it in the form of a quill shaft. Complete closure of the casing that houses the gears permits the use of pressure lubrication of the gears and bearings. It is customary to provide the gear set with its own circulating pump, cooler, filter, and necessary piping.

Couplings. Although some early reduction-gear installations were made with rigid connections between the engines and the pinion gears, all present-day installations are made with some form of coupling that will prevent the transmission of harmful vibration to the gears. The first form of vibration absorber was a quill-shaft drive. This was followed by several different types of mechanical flexible couplings, until the advent of the hydraulic coupling

Of late years there has been a decided trend toward the use of rotary blowers as scavenging air pumps. These blowers are of the Roots type and may be mounted on the engine and driven by gears, V-belts, or chains from the crankshaft, or they may be arranged for independent drive by electric motors. When attached blowers are used, some type of flexible or fluid coupling should be used in the drive in order to prevent damage by synchronous vibration or by inertia forces due to stopping and starting.

Crankcase Scavenging. In some types of engines the bottom ends of the pistons are used as scavenging pumps. The crankcase is made airtight and provided with suction valves. Each piston on the up stroke creates a partial vacuum in the crankcase and air is drawn in. On the downstroke this air is slightly compressed and, when the piston uncovers the scavenging ports, the air blows into the cylinder through a passage connecting the crankcase with the ports. With this arrangement the ratio of scavenging volume to power-cylinder volume can never be more than 1:1, and the mep in the cylinders is necessarily much less than when a higher scavenging ratio is used.

Starting Air System. Although all small engines and some fairly large ones used in connection with electric drive are started by electric motors, the method almost universally used for starting engines of more than 200 hp is by admitting air at 250 to 400 lb pressure to the cylinders through timed valves. Air for this purpose is provided by a compressor which discharges the air to tanks located at any convenient point in the engine room and connected to the starting valves in the cylinder heads.

This compressor is similar in construction to the injection-air compressor previously discussed, except that it is of two-stage construction because of the lower pressure to be handled. In some cases the compressor is built into the engine but driven by gears, chains, or V-belts; but in most installations, especially of large engines, it is independently operated, usually by an electric motor but in some cases by a separate auxiliary engine. Since the maintenance of an adequate supply of starting air is vitally essential, the air compressors should be installed in duplicate. If an attached compressor is used, a small independent unit should be provided; if no attached compressor is used, two and sometimes three units are installed.

In order to eliminate the possibility of the compressor's not being started in time during extended periods of maneuvering, automatic controls should be installed that will start and stop the compressors in accordance with pressure changes in the air tanks.

An excellent arrangement used on some U.S. Maritime Commission motorships is to provide three motor-driven compressors, two of which are of 48 cfm capacity each at 390 lb pressure, while the third is a make-up unit of 10 cfm capacity. Automatic controls are arranged so that when the pressure in the air tanks falls to 375 lb the small compressor starts; if the pressure falls to 350 lb one large compressor will start and the make-up compressor will stop; if the pressure falls to 300 lb, the second large compressor will start. All compressors will stop when the pressure in the tank reached 390 lb.

Air Starting Methods. Although every air starting system uses timed valves in the cylinder heads for admitting air into the cylinders at the right point in the cycle, there are several different methods in use for operating these valves. In every case the air main leading from the tanks is connected to each starting valve, but air is turned into these lines only during the times when the valves are in operation.

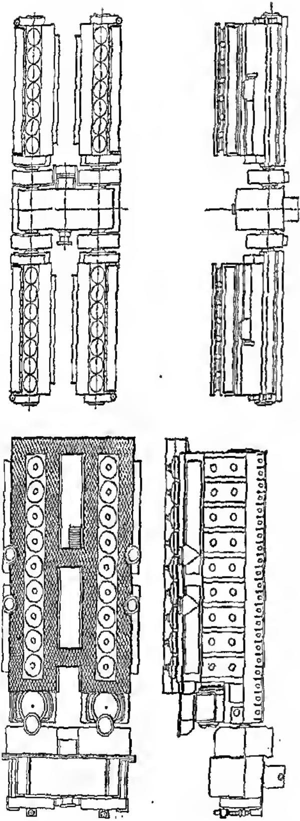

FIG. 15.—Typical arrangements of two-engine and four-engine gear drives. (*From D.E.M.A. Marine Diesel Standards.*)

In one arrangement the valves are operated by cams and levers, the levers being mounted on eccentric fulcrum bearings. Normally the rollers are held up clear of the cams but, when the eccentric bearings are rotated by the control gear, which at the same time operates to open the valve that admits air to the lines leading to the cylinders, the rollers drop onto the cams and the valves open and close in accordance with their timing under the influence of the cams and valve levers.

In another arrangement the starting valves in the heads are simply spring-loaded valves that open when air pressure in the valve body exceeds the spring pressure. Air is admitted to the valves at the right times by cam-operated control valves in a control unit at the operating station. In other designs the starting valve is operated by a piston in a cylinder incorporated in the valve body. Air is admitted to this cylinder through a small pipe line leading to a timed pilot valve in the control unit at the operating station. In every case the maneuvering gear is arranged so that air from the tanks is automatically turned on when the starting controls are moved to the start position, and cut off when they are moved to the run or stop positions.

Starting Air Capacity. The classification societies have established a requirement that diesel-powered vessels must have starting air-storage capacity sufficient for 12 consecutive starts of each engine. This is not an accurately measurable quantity because there are highly variable factors, such as temperature of the cylinders, tightness of rings, and skill of the operator, which have an influence on the amount of air required for each start.

As a starting point for a more definite evaluation, the amount of air-storage capacity should be related to the swept volume of the power cylinders. A ratio that is practical and will meet the requirement mentioned above is a storage capacity equal to 35 times the swept volume of one cylinder. With this as a basis the operating factors that have an influence must be considered. A large ship that normally executes but a few maneuvers, as when entering or leaving port, will require a much lower capacity ratio than a tug, which may often require a large number of starts when maneuvering in close quarters. Also a nonreversing engine used in connection with electric drive or reverse gears will require much less air capacity then a direct-connected reversing engine. In general the requirements for each different class of service are best determined on the basis of experience.

Air-compressor Capacity. The air-compressor capacity is also an indefinite quantity that has a relation to type of service. The controlling factor should be the length of time decided upon for the compressor to be able to fill the air tanks. The compressor capacity may then be determined by the following formula:

$$\text{cfm} = \frac{V \times p_t}{p_a T}$$

where V = volume of tanks, cu ft

p_t = pressure (absolute) to which tanks are to be charged

T = time allowed for charging, min

p_a = atmospheric pressure

Power Required for Compressors. The engine power absorbed by attached compressors, or the motor power required for independent drive, will vary with the pressure, number of stages, and free air capacity. The

and later the electromagnetic coupling. It is now common practice to use one or the other of these two latter types in reduction-gear-drives.

The advantage of both of these types of coupling lies in the fact that there is no mechanical connection between the engine and the gears it drives, and not only are the gears protected against engine vibration but also the engine is protected against sudden shocks due to the propeller's striking an obstruction.

Hydraulic Coupling. The principal elements in the hydraulic coupling, as shown in Fig. 16, are the impeller and the runner, which are two radially

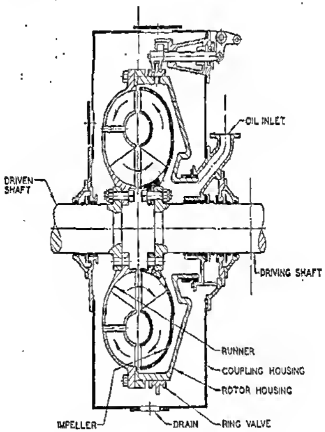

Fig. 16.—Section through hydraulic coupling.

vaned members with a concentric semicircular trough in each. When the two members are placed face to face, the outer shells and inner troughs form two concentric rings with an annular space between them. Both the runner and the impeller have an unequal number of radial vanes.

The impeller is mounted on the engine shaft and the runner on the pinion shaft, facing but not quite touching. A housing bolted to the runner encloses the back of the impeller and, by fitting closely around the driving shaft, forms a container for the working fluid, a mineral oil of 180 to 200 Saybolt viscosity. The entire unit is enclosed within an outer casing that forms a part of the fixed structure and is made oiltight by labyrinth packing where the shafts go through it.

horsepower theoretically required to compress 1 cu ft air under various conditions is shown in Table 1. Since the values given are for an assumed compression efficiency of 100 percent, whereas the actual efficiency is about 65 percent, these values should be multiplied by 1.54.

REVERSING SYSTEMS

Every engine connected to a propeller shaft should be provided with a means of reversing the direction of engine rotation or have a reverse gear interposed between the engine and the propeller shaft, in order to give the necessary backing motion to the propeller. It has been explained how the engine may be started by either air or electric motor but, if the engine must be started in either direction, only air starting is used. The basic requirement for reversing is that before starting the engine the valve-timing mechanism must be positioned to give the valves the correct timing for the desired direction of rotation. Since the valves are always operated by cams that have a definite angular relation to the crankshaft, the change of timing for changing the direction of rotation is accomplished by changing this angular relation.

Four-cycle Reversing. The method generally used for reversing the four-cycle engine is to provide two identical sets of cams on the camshaft, one set positioned to time the valves for ahead running and the other for astern. With the engine running in the ahead direction and the cam rollers resting on the ahead cams, reversal is accomplished by stopping the engine, shifting the camshaft in the direction of its length to bring the astern cams under the rollers, then starting the engine with air, after which rotation continues in the opposite direction in accordance with the changed timing of the valves.

Shifting of the camshaft is accomplished by one of several different methods, the most commonly used being by means of an air- or hydraulically-operated piston linked to the camshaft. This operation must be preceded by lifting the cam rollers off the cams, followed by lowering them onto the cams again after the shaft is moved, unless the cams are made with beveled edges that will permit the rollers to ride up on them.

The mechanisms involved are so linked together that the operations of raising the rollers, shifting the shaft, and lowering the rollers are executed by the movement of a single lever or handwheel at the control station. In some designs the starting air control and fuel control are also connected to this lever or handwheel, and the entire sequence of operations required for stopping, reversing, starting, and fuel admission is thus carried out by movement of the one lever or handwheel.

Two-cycle Reversing. In the case of the port-scavenged two-cycle engine the only timing that has to be changed for reversal is that of the fuel-injection pumps and air starting valves. If, however, exhaust valves are used, the timing of these also may have to be changed. In most two-cycle designs of the first type the air starting controls are separate from those for the fuel pumps, although they may be operated by the same control lever.

In this case it is necessary only to rotate the camshaft relative to the crankshaft about 30 deg, and the same cams used for ahead running are then in a position for astern timing. This relative rotation may be obtained by using an air-operated piston to slide a helical gear or turn one of the gears in the camshaft gear train, while the engine is stationary, enough to give the desired camshaft movement, or a lost-motion coupling may be used in the camshaft drive. In this latter case, when the engine is stopped and then started in the

An inlet pipe mounted on the casing, with a sliding fit on the inner housing, serves for admitting oil to the housing. Ports in the periphery of the housing, covered by a ring valve, serve for emptying the coupling rapidly when desired. This ring valve is interlocked with the inlet valve so that when one is open the other is closed.

With the impeller and runner assembled face to face, the vanes in the two form a continuous spiral passage around the central concentric ring. If the impeller is rotated with the coupling full of oil, centrifugal force causes the oil to flow radially outward, as shown by the arrows in Fig. 16, across the gap into the runner, then inward toward the lower part of the runner, and across the bottom gap into the impeller. Since the passage formed by the relative positions of the vanes is spiral, this movement causes the oil to travel continuously in a spiral path around the circumference of the coupling.

The kinetic energy generated as the oil flows outward and gains rotational velocity about the axis of the coupling, is released when the oil turns inward in the runner, and flows toward the axis of the coupling and its velocity is decreased. This energy is the force that causes the runner to turn. The torque input is equal to the torque output, and the power lost is represented by the slip between the impeller and the runner. Thus the efficiency of the coupling is the ratio between the speeds of the driving and the driven shafts.

In order to maintain a condition of difference in centrifugal force in the two members that will cause the oil to circulate as described, the coupling for any given power and speed must be selected so that there will be a difference of 3 percent between the speeds of the impeller and runner.

In addition to transmitting the engine power to the gears without vibration or torque fluctuation, the hydraulic coupling permits quick and easy disconnection of one engine without stopping the others, simply by dumping the oil. This is done by means of the peripheral ports and ring valve previously mentioned. If the ring valve is moved by the controls to uncover the ports, the inlet valve is closed and the centrifugal force throws the oil out through the ports, thus bringing the driven member to rest even though the driver continues to turn. On installations where it is not necessary to dump the oil in order to disconnect the engine while running, another type of hydraulic coupling, known as the "traction" coupling, is popular since it is cheap to purchase and install. This coupling has exactly the same driving members as the dump coupling but does not have the filling or dumping features with the coolers, pumps, and piping. The coupling must be filled through a plug with the engine at rest and dumped in the same manner if it is desired to disconnect the engine. It is calculated to have enough cooling surface itself to keep the oil within operating limits.

Electromagnetic Coupling. The electromagnetic coupling, or electric coupling, as it is commonly called, offers another method of driving the reduction gears without any mechanical connection between the engine shaft and the pinion shaft. In construction it resembles an induction motor, having an inner member or armature mounted on the engine shaft and an outer member, carrying salient field poles, mounted on the pinion shaft. The inner member is positioned inside the circle of field poles so that there is an air gap of 0.2 to 0.4 in. between its periphery and the faces of the field poles, as shown schematically in Fig. 17. The inner member has a squirrel-cage winding similar to an induction-motor armature. When the field of the outer member is excited by direct current through collector rings and brushes, a strong magnetic flux is set up which causes the inner member to rotate with the field at the speed of the field, less the slip, which amounts to 1.3 to 1.5 per cent.

The power required for excitation amounts to about 1 percent of the power transmitted through the coupling and the maximum torque that can be transmitted by the coupling is about 200 percent of normal. If the load on the gears and the propeller shaft for any reason exceeds this amount, the coupling will fall out of step and the load on the engine will be reduced. Also, the torque transmitted has no relation to the speed of rotation of the unit as a whole but depends upon the relative speeds of the two parts of the coupling; hence the coupling can transmit the full torque exerted by the engine even when the engine is operating at slow speed.

As in the case of the hydraulic coupling, there is no mechanical connection between the engine shaft and the pinion shaft; therefore pulsations of torque and critical vibrations do not reach the gears, and sudden shocks caused by the propeller striking an obstruction do not reach the engine crankshaft. Also, any one engine can be disconnected instantaneously from the gear set simply by opening a switch in the excitation circuit.

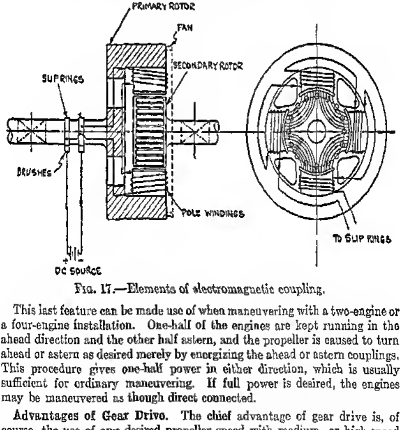

FIG. 17.—Elements of electromagnetic coupling.

This last feature can be made use of when maneuvering with a two-engine or a four-engine installation. One-half of the engines are kept running in the ahead direction and the other half astern, and the propeller is caused to turn ahead or astern as desired merely by energizing the ahead or astern couplings. This procedure gives one-half power in either direction, which is usually sufficient for ordinary maneuvering. If full power is desired, the engines may be maneuvered as though direct connected.

Advantages of Gear Drive. The chief advantage of gear drive is, of course, the use of any desired propeller speed with medium- or high-speed engines. There are incidental advantages such as less headroom required, and the facility with which repairs or examination of one engine at a time can be carried out at sea without stopping the ship. Also, the use of smaller and lighter engines reduces the size of parts to be handled and provides greater flexibility. The chief disadvantage of gear drive is the greater cost of the installation as compared with a direct-drive plant of the same power, except when very low propeller speeds are used.

(*b*) Transcendental Equations:
exponential equations, *e.g.*, $2^x = 32$ (root: $x = 5$); $2^x = -32$ (no root); trigonometric equations, *e.g.*, $10 \sin x - \sin 3x = 4$ (roots: 30°, 150°).

Legitimate Operations on Equations. An equation which is true for a particular value of x will remain true for that value of x after any one of the following operations is performed:

Adding any quantity to both sides; subtracting any quantity from both sides; transposing any term from one side to the other, provided its sign be changed; multiplying or dividing both sides by any quantity which is not zero; changing the signs of all the terms; raising both sides to any positive integral power; extracting any odd root of both sides; extracting any even root of both sides, provided the $\pm$ sign is used; taking the logarithms of both sides (both sides being positive); taking the sin, cos, tan, etc., of both sides.

Notice, however, that the new equation obtained by some of these operations may possess "additional roots" which did not belong to the original equation. This occurs especially when both sides are squared; thus, $x = -2$ has only one root, namely, -2; but $x^2 = 4$, obtained by squaring, has not only the root -2 but also another root, $+2$.

Equations of the First Degree (Linear Equations). Solution: Collect all the terms involving x on one side of the equation, thus: $ax = b$, where a and b are known numbers. Then divide through by the coefficient of x, obtaining $x = b/a$ as the root.

Equations of the Second Degree (Quadratic Equations). Solution: Throw the equation into the standard form $ax^2 + bx + c = 0$. Then the two roots are:

$$x_1 = \frac{-b + \sqrt{b^2 - 4ac}}{2a} \qquad\qquad x_2 = \frac{-b - \sqrt{b^2 - 4ac}}{2a}$$

The roots are real-and-distinct, coincident, or imaginary, according as $b^2 - 4ac$ is positive, zero, or negative. The sum of the roots is $x_1 + x_2 = -b/a$; the product of the roots is $x_1x_2 = c/a$.

GRAPHICAL SOLUTION. Write the equation in the form $x^2 = px + q$, and plot the parabola $y_1 = x^2$, and the straight line $y_2 = px + q$. The abscissæ of the points of intersection will be the roots of the equation. If the line does not cut the parabola, the roots are imaginary.

Equations of the Third Degree with Term in x^2 Absent. Solution: After dividing through by the coefficient of x^3, any equation of this type can be written $x^3 = Ax + B$. Let $p = A/3$ and $q = B/2$. The general solution is as follows:

Case 1. $q^2 - p^3$ positive. One root is real, namely

$$x_1 = \sqrt[3]{q + \sqrt{q^2 - p^3}} + \sqrt[3]{q - \sqrt{q^2 - p^3}}$$

the other two roots are imaginary.

Case 2. $q^2 - p^3 =$ zero. Three roots real, but two of them equal.

$$x_1 = 2\sqrt[3]{q},\ x_2 = -\sqrt[3]{q},\ x_3 = -\sqrt[3]{q}$$

Case 3. $q^2 - p^3$ negative. All three roots real and distinct. Determine an angle u between 0 and 180°, such that $\cos u = q/(p\sqrt{p})$. Then

$$x_1 = 2\sqrt{p}\cos(u/3),\ x_2 = 2\sqrt{p}\cos(u/3 + 120°),\ x_3 = 2\sqrt{p}\cos(u/3 + 240°).$$

GRAPHICAL SOLUTION. Plot the curve $y_1 = x^3$, and the straight line $y_2 = Ax + B$. The abscissæ of the points of intersection will be the roots of the equation.

Equations of the Third Degree (General Case). Solution: The general cubic equation, after dividing through by the coefficient of the highest

power, may be written $x^3 + ax^2 + bx + c = 0$. To get rid of the term in x^2, let $x = x_1 - a/3$. The equation then becomes $x_1{}^3 = Ax_1 + B$, where $A = 3(a/3)^2 - b$, and $B = -2(a/3)^3 + b(a/3) - c$. Solve this equation for x_1, by the method above, and then find x itself from $x = x_1 - (a/3)$.

GRAPHICAL SOLUTION. Without getting rid of the term in x^2, write the equation in the form $x^3 = -a[x + (b/2a)]^2 + [a(b/2a)^2 - c]$, and solve by the graphical method.

General Properties of Algebraic Equations. An algebraic equation of the nth degree in x is an equation of the type

$$a_0x^n + a_1x^{n-1} + a_2x^{n-2} + \dots + a_{n-1}x + a_n = 0$$

where the a's are any given numbers (a_0 not zero), the expression on the left being called a **polynomial** of the nth degree in x. Such an equation will, in general, have n roots; but some of these n roots may be equal, and some may be imaginary. **Imaginary roots** always occur in pairs.

If the equation is written in the form: (a polynomial in x) $= 0$, then (1) *if a is a root of the equation, $x - a$ is a factor of the polynomial; (2) if the* polynomial can be factored in the form $(x - p)(x - q)(x - r) \dots = 0$, each of the quantities $p, q, r, \dots$ is a root of the equation; (3) if x is very large (either positive or negative), the higher powers of x are the most important; (4) if x is very small, the higher powers may be neglected.

Short Method of Substitution in a Polynomial. To find the value of $4x^4 - 14x^3 + 23x - 26$ when $x = 3$, for example, first arrange the terms in order of descending powers of x, and write the detached coefficients, with their signs, in a row, taking care to supply a zero coefficient for any missing term, including the constant term. Then, beginning at the left, bring down the first coefficient; multiply this by 3, and add to the second coefficient; multiply this result by 3 again, and add to the third coefficient; and so on. The final result, -11, is the value of the polynomial when $x = 3$.

4	−14	0	23	−26	(3
	12	−6	−18	15	
4	−2	−6	5	−11	

Short Method of Dividing a Polynomial by x − a. The device just explained gives not only the value of the polynomial when $x = 3$, but also the result of dividing the polynomial by $x - 3$. Thus, in the case illustrated, the quotient is $4x^3 - 2x^2 - 6x + 5$ and the remainder is -11. That is, $4x^4 - 14x^3 + 0x^2 + 23x - 26 = (x - 3)(4x^3 - 2x^2 - 6x + 5) - 11$.

Exponential Equations. To solve an equation of the form $a^x = b$, take the logarithms of both sides: $x \log a = \log b$, whence $x = (\log b)/(\log a)$. For example, if $3^x = 0.4$, $x = \log 0.4/\log 3 = (0.6021 - 1)/0.4771 = -0.3979/0.4771 = -0.8340$. Notice that the complete logarithm must be taken, not merely the mantissa.

Trigonometric Equations. (1) To solve $a \cos x + b \sin x = c$, where a and b are positive: Find the acute angle u for which $\tan u = b/a$, and the angle v (between 0 and 180°) for which $\cos v = c/\sqrt{a^2 + b^2}$. Then $x_1 = u + v$ and $x_2 = u - v$ are roots of the equation.

(2) To solve $a \cos x - b \sin x = c$, where a and b are positive: Find u and v as above. Then $x_1 = -(u + v)$ and $x_2 = -(u - v)$ are roots of the equation.

General Method of Solution by Trial and Error. This method is applicable to a numerical equation of any form, and can be carried out to any desired degree of approximation. It is especially useful when a first approximation to a root is already known. Write the equation in the form

ELECTRIC DRIVE

From the standpoint of machinery arrangement, the diesel-electric is the most flexible of all drives. It permits dividing the power plant into as many units as desired, and the propulsion motor is the only principal element in the plant that is limited to a fixed location by its function. The generating sets that furnish power for the motor may be located at any point in the ship that is most convenient or desirable and may be placed remote from the propulsion motor. Also, the controls may be located at any desired point. Its principal disadvantage is its loss in efficiency due to losses in generators and motors, amounting to approximately 15 per cent.

The essential elements in such a plant include one or more diesel-driven generators, a propulsion motor, a source of current for excitation, and control equipment. The engine driving the generator is required to run in only one direction and, therefore, needs no reversing gear.

It can be designed to run at any desired speed, thus permitting the use of lightweight engines. Earlier practice called for constant-speed engines but, in present-day installations, it is common practice to arrange the engine for variable-speed operation. In this case the engine is operated at about half speed and all propeller speed variations are obtained by varying the voltage of the propulsion motor field, up to half speed, at which point all resistance is out of the field circuit. Beyond that point, further increases of speed are obtained by increasing the engine speed.

Generators. The generators are shunt-wound, separately excited d-c machines, with the exciter armatures mounted on the extended shaft of the generators or mounted above the main generators and driven by belts. Since the exciter must deliver constant voltage while the engine speed varies, a voltage regulator is required. Usually the exciter has a capacity in excess of the power required for excitation, in order that it may supply current for operating auxiliaries.

Propulsion Motor. The propulsion motor is a separately excited, shunt-wound machine and, when attached directly to the propeller shaft, must necessarily operate at slow speed. This calls for a comparatively large motor and, in order to reduce the diameter, it is customary to use a double-armature motor which is in effect two motors placed side by side. In later installations the use of large, heavy motors is avoided by the placing of reduction gears between the motors and the propeller shaft. This permits the use of high-speed motors of small size.

Controls. For control of the propulsion-motor speed by the variable voltage method, with the engine running at constant speed, the armatures of the motor and main generators are connected in series and their fields are independently connected to the excitation circuit. The motor field is excited at a constant value, and its speed is varied by varying the intensity of the generator field. Increasing the generator field increases the generator voltage impressed on the motor. Since the motor field is constant, the speed of the motor will vary directly as the impressed voltage. In types of service in which it is desirable to enable the propeller to absorb full engine power while turning at slow speed, as in tug operation, the amount of torque developed by the motor can be adjusted by the use of a rheostat in the motor field circuit. Reversal of the motor is accomplished by reversing the direction of the generator excitation current. The resulting reversal of generator voltage causes the motor to reverse its direction of rotation.

Available Fuels. The purchaser who buys diesel fuel in large quantities can usually obtain oil to any desired specification, but the transient vessel or the small consumer that bunkers from oil company stock in any given port must take whatever is available.

Posted prices for diesel fuel in New York Harbor apply to a fuel of 30 A.P.I. gravity or over, carbon content less than 1 percent, and a viscosity of about 40 SSU at 100 F. This is a fuel suitable for high-speed engines but not needed for slow-speed units. A grade of oil known as heavy marine diesel fuel can be obtained for 20 to 25 cents per barrel less that has a gravity of about 20 A.P.I., viscosity 100 SSU at 100 F carbon about 1 percent, and a cetane number as high as 40.

Effect of Fuel Price. Roughly, the cost of fuel amounts to about 50 percent of the operating cost of the average cargo ship and is thus the item that offers the most attractive target for efforts at saving. Aside from all other considerations, such as increased cargo capacity due to the smaller weight of fuel that must be carried, the diesel engine would offer a large saving in the cost of fuel, as compared with the equivalent steam plant if both used the same kind of fuel. Although there is a definite trend toward the use of boiler

Alternating-current Drive. Although most diesel-electric drives utilize direct current, there is a growing trend toward the use of alternating current, because of the greater efficiency of the a-c plant and the lower cost, lower weight, and simplicity of the equipment. The disadvantages of alternating drive are that it is similar to a fixed-ratio gear drive. For instance, if two generator units are driving a single propulsion motor at rated full speed and for any reason it becomes necessary to stop one generator, the other generating unit will automatically have to slow down to approximately 63 per cent of its top rating in order not to be overloaded. This complies with the law that the horsepower varies as the cube of the speed. With the d-c drive this would not be necessary, for by changing the field current the remaining generating unit could be operated at its full capacity without any injury to itself and thus bring the propeller up to 79 per cent of full speed. The principal elements in the a-c system are one or more salient pole generators and a synchronous motor on each propeller shaft.

The general principle of operation is to start the engines, bring them up to idling speed, then synchronize the generators, and close the reversing switch for the direction desired. The motor will then operate as an induction motor with its fields short-circuited; when it comes up to the same synchronous speed as the engines, the motor field current is applied and the motor brought into step with the generators.

With the generators and motor in step, any increases of speed may be obtained by increasing the speed of the engines. Below the idling speed further speed reductions are obtained by operating the motor as an induction motor with voltage low enough to produce slip. When maneuvering ahead and astern, the required torque is obtained by overexciting the generator fields. A greater range of speed changes can be obtained if the motor is provided with two sets of poles.

ECONOMICS OF THE DIESEL ENGINE

Considered on the basis of its ability to convert energy released from the fuel in the form of heat into power available at the crankshaft for performing work, the diesel engine is the most efficient prime mover yet produced. Between this initial conversion of energy and the final book balance between the cost of producing power and the income derived from the application of this power, there are several variable factors that should be taken into account. This is particularly true in marine service, and it is impossible to establish any one set of figures that can be given blanket application for comparing the economy of diesel-propulsion machinery with other types used in marine service. There are, however, certain basic factors that can be evaluated for use in establishing a figure for over-all economy under any given conditions of operation.

Fuel Consumption. Fuel consumption of marine diesel engines is sometimes stated in terms of pounds of fuel consumed per indicated horsepower per hour, because the only power that can be measured after the engine is installed in the ship is that determined from indicator cards. The only power the shipowner is interested in, however, is that available at the shaft that can be used for income-producing work. The fuel consumption, then, should be expressed in terms of pounds of fuel per brake horsepower per hour. The terms brake horsepower and shaft horsepower are used synonymously, but the former is usually preferred because the economy of the engine is determined when it is run in the shop and the load applied by some form of brake, usually

a water brake. If a more precise definition of shaft horsepower is taken to mean only the power delivered to the propeller, the friction in thrust bearings and line-shaft bearings must be deducted. Also a deduction must be made for losses in diesel-electric drives and for slip of coupling in gear drives. The amount of brake horsepower that can be obtained from a given quantity of fuel is a true measure of the engine's economy.

The amount of fuel consumed per brake horsepower will vary between narrow limits with different engines, but it should never be more than 0.4 lb per bhp-hr at normal full load for the engine without attached auxiliaries. Many engines use less than this. The records of some engines in service show a normal consumption of 0.334 lb per bhp-hr. An interesting characteristic of the diesel engine is the small difference in fuel consumption of different sized engines. The graph of full-load consumption for units of various sizes, from 5 to 15,000 hp, is practically a straight line.

Lubricating-oil Consumption. Far more variable than fuel consumption is the amount of lubricating oil used by the engine. As explained on p. 1337, the oil applied to the cylinder walls is not recoverable but is burned in operation. There is no way of determining definitely, while the engine is running, whether the amount of lubricating oil being fed into the cylinders is enough, too little, or too much. Therefore, the lubricator feed must be adjusted on the basis of past experience or judgment and is most often likely to be too much. In general it may be assumed that the two-cycle engine will require more oil than the four-cycle for cylinder lubrication.

There will also be wide variations in the amounts of oil used in the bearing lubricating system. In a large crosshead type engine in which the cylinders are separated from the crankcase by a diaphragm, there will be less oil lost by being drawn up into the cylinders and burned than will be the case with a trunk-piston engine, especially if the latter is of the high-speed type. In both engines the amount of oil lost by leakage will depend upon the degree of tightness of crankcase doors and joints throughout the system and will accordingly vary with the quality of attendance the engine receives and to some extent upon the provisions made by the designer for oil tightness.

These variable conditions account for the variation of oil consumption mentioned. Expressed in terms of the number of horsepower-hours produced per gallon of lubricating oil used, the consumption may vary from about 1 gal per 1,000 hp-hr in small, high-speed engines to 1 gal per 10,000 hp-hr in large, slow-speed units. Since most engines in service are of small size, it will be found that a fair average consumption by existing engines is somewhere between 1 gal per 1,500 hp-hr and 1 gal per 2,000 hp-hr. If small high-speed engines are excluded, the average consumption will be 1 gal per 3,000 to 5,000 hp-hr.

Effect of Wear. The variations noted and their causes apply to engines in normally good operating condition. Further variations will be introduced by the condition of the engine, particularly in regard to piston ring and liner wear. Such wear in a trunk-piston engine will usually result in an increase in the amount of crankcase oil drawn up into the cylinders and burned. Also the resulting blow-by of gases into the crankcase causes a large amount of oil vapor to be blown out through the crankcase breather pipe.

Over-all Economy. The fact that the diesel engine is inherently the most efficient prime mover yet devised is not in itself a guarantee that the diesel-propulsion plant will be the most economical under all conditions. Numerous other factors, some within the plant and others outside but related

oil for diesel fuel, most diesel engines use a refined fuel costing considerably more than boiler oil.

This difference in cost has the effect of reducing the comparative net economy of the diesel plant, and the greater the difference between the costs of the two fuels, the greater this reduction will be. Fuel prices vary in different ports. At time of writing, standard diesel fuel costs 60 percent more than boiler fuel in New York Harbor but in Los Angeles harbor the difference is only 30 percent. It is obvious that in the case of two ships, one a steamer and the other a motorship, both with machinery plants of the same total horsepower, the higher this percentage difference is, the nearer the steamer will approach the motorship in cost of power. The point at which the cost difference disappears can be determined by a simple calculation.

Assuming two ships of 4,000 bhp, one using Bunker C fuel and the other diesel fuel, and basing their respective fuel consumptions on reports of the service performance of efficient ships of their types, the steamer will consume 13,020 Btu per shp per hr and the motorship will consume 7030 Btu. The other data may be tabulated as follows:

	Steamer	Motorship
Gravity of fuel, A.P.I.	11	29
Pounds per bbl	343	308
Heat content, Btu per lb	18,500	19,000
Price per bbl	$1.10	$1.45
Btu per bbl	6,345,500	5,852,000
Cost per million Btu, cents	17.2	24.8
Btu per shp	13,020	7,030
Total Btu per hr	52,080,000	28,120,000
Cost of fuel per hr	$8.95	$6.97

If the cost of fuel for the steamer is $8.95 per hour, the motorship can pay as much as 895/18.2 = 31.8 cents per million Btu, or $1.86 per barrel, before its hourly fuel cost will equal that of the steamer. On a Btu basis this shows that the motorship can pay $\frac{31.8 - 17.2}{17.2} = 85$ percent more for its fuel than does the steamer without its fuel bill exceeding that of the steamer. This relation will hold true in any port in the world, regardless of relative fuel prices, as long as the relative consumptions are as stated.

It is obvious from the foregoing discussion that the difference in costs of fuel used for steamers and for diesel-powered ships penalizes the latter to a degree that becomes greater as the disparity in prices increases until, when the 85 percent point is reached, the two are on an equal footing in regard to fuel cost. This indicates that it is very much to the advantage of the diesel engine to avoid the use of high-priced special fuel and burn the same type of oil that is burned under boilers.

Use of Heavy Fuel. The economic penalty imposed on the motorship by the use of high-grade diesel fuel has created an increasing tendency toward the use of the heavier grades commonly used as boiler fuel and loosely classified as Bunker C. This does not identify any one grade of oil since it includes those varying in gravity from 10 to 17 deg or more A.P.I. and having Saybolt viscosities from 2,000 to 4,000 at 100 F. Such oils usually contain considerable abrasive matter that tends to increase the rate of wear of liners and

to its operation, have an influence on its economic balance. The over-all economy of the entire propelling plant is the matter in which the ship operator is most interested. Among the factors that enter into it, the principal ones are fuel oil and lubricating-oil consumption of main and auxiliary engines and cost of maintenance.

These determine the variable costs that must be added to such fixed charges as interest on investment, depreciation charges, insurance, and crew cost, in determining the final cost per unit of power delivered to the propeller. The rate of fuel consumption may prove to be less important than the kind of fuel consumed. The ability of an engine to burn a heavy fuel that is cheaper than high-grade diesel fuel may spell the difference between profit and loss.

Numerous factors enter into the cost of maintenance, the first being the quality of design. Assuming that the engine is correctly operated, the rate of wear is strongly influenced by this design factor, as is also the frequency of parts breakage. Accessibility is an important factor in maintenance cost and should be given consideration in the original design and the installation plan. The most accessible engine may be made extremely difficult to keep in good operating condition if no consideration is given to accessibility in designing the installation arrangement in the ship.

The items mentioned in the foregoing are merely indications of the wide scope that would have to be covered if any detailed analysis of over-all economy is to be made. A more specific means of favorably affecting over-all economy is by utilization of that part of the heat content of the fuel that is discharged to the atmosphere in the exhaust without doing useful work.

WASTE-HEAT RECOVERY

The heat balance of the average diesel engine shows that about 30 percent of the total heat supplied is carried away in the exhaust and accordingly wasted. The amount of this waste heat can be indicated by assuming a 1,000-hp engine to use 0.4 lb fuel per hp per hr, and the fuel to have a heating valve of 18,500 Btu. Then if 30 percent of the heat is carried away in the exhaust, the total amount lost will be $H = 1{,}000 \times 0.4 \times 18{,}500 \times 0.30 = 2{,}220{,}000$ Btu per hr. Although not all of this heat is recoverable, enough of it can be recovered by means of an exhaust-gas boiler to increase appreciably the over-all economy of the plant.

The amount of heat that theoretically can be recovered in such a boiler is the difference between the total heat in the gases at the temperature at which they leave the engine and their total heat at the temperature of the steam at the pressure carried in the boiler. It is not practicable, however, to effect a transfer of heat that will reduce the gases to the same temperature as the steam. About the best that can be done is to reduce the gas temperature to about 75 deg higher than that of the steam in the boiler. It follows, then, that the higher the steam pressure carried in the boiler the less the amount of heat that can be recovered from the gases.

Amount of Heat Recoverable. To estimate the amount of heat that can be recovered, the pressure desired, the boiler efficiency, and the temperature of the gas leaving the engine must be known. Usually the efficiency of the boiler is not accurately known, but a figure can be assumed for the difference in temperature between the steam and the gas leaving the boiler, such as the 75 deg previously mentioned.

rings, a condition aggravated by the fact that, if the oil is not properly conditioned before injection into the cylinder, the resulting reactions interfere with lubrication.

It has been definitely established that engines with large- or medium-bore cylinders, with correspondingly large combustion-chamber volume, experience no trouble in burning heavy oil satisfactorily, but as the cylinder bore becomes smaller and the revolutions higher more difficulty is experienced. This has led to the conclusion in some quarters that on oceangoing ships two different grades of fuel should be carried, one for the main engines and one for the auxiliary engines. Other informed opinion holds that this is not necessary because engines of the sizes used for auxiliary service in motorships of average size can operate on heavy fuel if the two prime requisites—cleaning of the fuel and heating to the proper degree—are provided.

Liner Wear. The principal deterrent to the use of heavy fuels has been the resulting increase in rate of liner wear. Renewal of liners is the most expensive item in maintenance costs and, if it is required too often, may nullify the gains resulting from the use of cheap fuel. On the other hand the renewal frequency, even though it is greater than when standard diesel fuel is used, may be considerably overbalanced by the saving in fuel cost resulting from the use of the cheaper oil. The fuel bill with standard fuel may in two years amount to as much as the first cost of the engines and, if this bill can be reduced by even a small percentage, it will more than pay for the increased cost due to more frequent liner renewal.

Liner wear resulting from abrasive impurities can be dismissed as unnecessary because the necessity for cleaning is well known and the equipment available for that purpose is readily available. Experiments reported by Broeze and Gravesteyn indicate that although carbon and ash content have some influence on rate of wear, the sulfur content is the principal factor, with incomplete combustion second to it. These experimenters reported that when the sulfur content is more than 1 percent the formation of sulfur trioxide causes corrosion in the combustion space that creates the effect of liner wear.

Incomplete combustion is preventable by strict observance of the requirements for correct heating, adequate compression pressure, correct cylinder temperature, and correct timing of injection. The most promising method of preventing the corrosion due to sulfur is by the use of chromium-plated liners. The investigators referred to found that with a very low grade of fuel, containing high percentages of sulfur, carbon, and ash, chromium-plated liners showed a rate of wear only one-tenth of that of unplated liners, using the same fuel.

Fuel Conditioning. The heating of oil to reduce its viscosity is the first step in the conditioning of heavy fuel. An initial heating in the bunkers may or may not be necessary to make it fluid enough to be handled by the transfer pump, but it is desirable to heat the oil before it is passed through the centrifuge for cleaning. After cleaning, further heating is required to reduce the viscosity enough for the fuel-injection pumps to be able to handle it. Maintenance at an even temperature is facilitated if the fuel-supply system is arranged for continuous circulation of oil through the heaters. A viscosity that permits ready passage of the oil through the fuel-injection pumps is also low enough for atomization by the injection valves.

To prevent a fall in temperature and rise in viscosity during the passage of the oil from the pumps to the injection valves, each connecting tube should

Example. Consider the case where the gas leaves the engine at a temperature of 700 deg and steam at a pressure of 100 lb is desired. Since the temperature of the steam is 337 F, the temperature of the gas leaving the boiler will be 337 + 75 = 412 F and the temperature drop will be 700 − 412 = 288 F. If the air temperature is assumed to be 70 deg, the percent of heat recovered will be 288/700 − 70 = 45.7 percent. In the case of the 1,000-hp engine cited previously the heat recovered will be 2,220,000 × 0.457 = 1,014,540 Btu per hr.

The amount of heat required to produce 1 lb steam at 100 lb pressure, assuming a feed-water temperature of 140 deg, will be 880 + 337 − 140 = 1077 Btu, and the amount of steam per hour that could be produced by the 1,000-hp engine would be 1,014,540/1077.4 = 942 lb. This amount represents a rate of production of 0.942 lb per bhp per hr.

A more detailed method of calculation is presented by Gregson, an example of which is that for a four-cycle engine consuming 0.4 lb fuel per bhp per hr and having an exhaust gas temperature of 740 F. Steam is generated at a pressure of 160 lb, and the gas leaving the boiler has a temperature of 370 + 70 = 440 F. The excess air is taken as 125 percent, corresponding to a CO_2 content of 600 percent in the gas, and the boiler efficiency is 95 percent.

Btu recovered per bhp per hr = weight of gas per hr × temperature drop × specific heat × 0.95. With a specific heat of 0.24 this becomes

$$\text{Btu (hr) (bhp)} = 0.4 \times 32.84 \times 300 \times 0.24 \times 0.95 = 900$$
$$\text{Steam per hr per bhp} = {}^{900}\!/_{960} = 0.93 \text{ lb}$$

Exhaust-gas Boiler. Since there is no radiant-heat effect in the exhaust-gas boiler and the heat flow is by conduction only, the heating surface should be large and the gas velocity high, with the flow path arranged to break up the gas stream. The types of boilers in use include those with horizontal tubes of hairpin shape; those using thimble tubes projecting from a cylindrical shell and closed at their outer ends; the tubular type, similar to a fire-tube boiler; the bent-tube type, in which the tubes are arranged as flat coils laid one on top of the other; and the type in which a water jacket surrounding the exhaust muffler is used to produce steam.

Steam from the exhaust-gas boiler is, of course, available only when the engine is in operation, and the rate of evaporation will decrease when the engine is operated at reduced speeds. For these reasons the greatest benefit from heat reclamation is obtained on voyages long enough to call for continuous operation of the engine for extended periods.

The greatest economy is obtained when the steam produced is used to operate the auxiliaries ordinarily required at sea, such as the steering engine, oil and water pumps, and lighting generator. A most desirable arrangement is to have the auxiliaries driven by electric motors and supply them with current from a steam-turbine-driven generator, operated by steam from the exhaust-gas boiler, with a diesel-driven generator as a stand-by. They can then be operated with current from the turbogenerator or the diesel generator as desired.

By arranging the exhaust-gas boiler for oil firing it can be used in port or its rate of evaporation can be maintained at a maximum during periods of slow-speed operation at sea. This latter possibility exists only if the boiler is designed with a separate combustion chamber isolated from the gas-inlet chamber. Such a boiler is in most cases simply two separate boilers with a common steam drum or steam space.

An arrangement that has been used with success in some recent tankers utilizes an exhaust-gas boiler of this type, in connection with automatic controls. Normally the b

be paralleled by a small steam pipe and the two wrapped together and insulated. As stated before, the temperature of the oil should be high enough to lower its viscosity to about 200 SSU.

To ensure complete combustion, the compression pressure should be raised to about 25 lb higher than when operating with light fuel. Also the jacket-water temperature should be maintained as high as is consistent with good lubrication and freedom from piston seizure. No specific temperature for the jacket water can be stated, since it will vary with different engines and can be determined only by trial in each case. The ignition lag is usually greater and the rate of combustion slower with heavy grades of oil. For this reason the time of injection should be advanced, the amount of advance to be determined by trial.

VIBRATION AND NOISE SUPPRESSION

The vibration occurring in any reciprocating engine has its origin in the movement of the reciprocating parts and the force applied periodically to the piston to accelerate these parts. This force can be calculated by the fundamental formula:

$$F = \frac{12WV^2(\cos d + r \cos 2d/l)}{Agr}$$

where W = total weight of reciprocating parts
V = velocity of crank, fps
d = angle between crank and center line through cylinder
l = length of connecting rods
A = area of piston, sq in.
g = acceleration due to gravity
r = radius of crank

If the values of F obtained by this formula are plotted against crank angle, the result will be a sine curve with an amplitude of 180 deg between maximum plus valves and maximum minus valves, as shown by curve a in Fig. 18. If the expression outside the parenthesis and the one inside it are calculated separately and plotted, the two curves b and c will be obtained, the first representing the influence of the reciprocating masses considered concentrated at the crankpin and the second the influence of the angularity of the connecting rod. These forces are the first and second harmonics, and it will be noted that the second has twice the frequency of the first and much less amplitude. By accurate calculation of the centrifugal force, succeeding harmonics of increasing frequency and decreasing amplitude can be plotted, as shown by curve d which is the fourth harmonic. Harmonics above the fourth order have little influence on vibration and may be neglected.

Cylinder Combinations. Since the forces causing vibration, as described in the foregoing, occur in each cylinder and the phase relation of these different sets of forces depends on relative crank positions, it is evident that the number of cylinders in an engine and the crank settings have an important influence on vibration. In a three-cylinder engine with cranks 120 deg apart, the first, second, and fourth harmonics are completely balanced, but there are couples in the vertical and horizontal planes that cause vibration. In the six-cylinder four-cycle engine, which is in effect two three-cylinder engines, these couples will act in opposite directions and cancel each other

steam being generated is insufficient to meet the demands of the auxiliaries, the pressure falls and at a predetermined pressure the controls cut in the oil burner. When the pressure rises to a given point, the burner cuts out.

AUXILIARIES

In order to keep the diesel engine in operation and supply such services as lubrication and cooling of the engine, certain auxiliary equipment is required. Also, diesel generators must be provided for supplying power to operate deck machinery, such as steering engine, anchor windlass, capstans, and deck winches; also to supply lighting current, domestic water, sanitary water, and water for fire protection, as well as power for operating bilge pumps and refrigerating and ventilating equipment. Some of this auxiliary equipment must be in operation at all times while the propulsion engine is running, and some is required to be operated only intermittently.

Independent Auxiliaries. It is universal practice to use electric-motor-driven auxiliaries in all cases, except when they are attached directly to the engine, and in all large ships the current for their operation is provided by diesel-driven generator sets. The amount of generating capacity required will vary widely according to the type of ship. In the case of a cargo ship the controlling factor will be the amount of power required for operating cargo winches; in the passenger ship it will be the power required for the hotel load, *i.e.*, service to passengers, that will control.

This total power should be divided between two or more diesel-generator sets for the sake of economy in operation, owing to the fact that only a fraction of the total power is required most of the time. A cargo ship or tanker while in port will require a large amount of power to operate winches or cargo pumps, and all the generators must be in operation; at sea, one will usually carry all the load. The auxiliary diesels are thus enabled always to operate at somewhere near their rated load if the total maximum power is divided between several units.

The auxiliaries required to keep the engine in operation are the lubricating-oil-circulating pump, the fresh-water-circulating pump, the raw-water-circulating pump, and sometimes a fuel-booster pump with coolers in the oil and water circuits. If the open type of cooling system is used, the raw-water pump and water cooler are dispensed with. The water pumps are usually of the centrifugal type, and the lubricating-oil pump of the rotary or gear type. As a matter of precaution, both are usually installed in duplicate.

A form of diesel unit widely used on small diesel vessels is the so-called auxiliary set, which combines in one unit all the principal auxiliaries other than the pumps mentioned in the foregoing. It consists of a small diesel engine, a generator, air compressor, general service pump, and the oil and water pumps for the engine, all mounted on a common base. Connection to the engine is made by clutches so that any one or more of the units in the set may be operated at the same time.

Engine-driven Auxiliaries. Some accessory equipment such as fuel injection pumps, cylinder lubricators, and, in air-injection engines, the air compressor, have always been built into the engine structure and driven by the engine. Present-day design of engines below approximately 1,500 hp extends this practice to other auxiliaries so that in some types of vessels no diesel generator need be in operation when the main engine is running. There is no engineering reason why this should not be done in all cases, but

if cranks 1 and 6 are in phase and if 2 and 5 and 3 and 4 are likewise paired. The six-cylinder engine is thus inherently balanced.

Torsional Vibration. Vibration becomes synchronous when the vibrating impulses applied to any part have a frequency that coincides with the natural frequency of that part. The speed at which this condition is set up in an engine is known as the **critical speed**, and it becomes most serious when synchronous torsional vibration is set up in the crankshaft. Torsional vibration is the vibration set up in a shaft when the torque applied to the shaft causes it to twist and the stress thus set up causes it to untwist. A single impulse applied in this way will be followed by alternate twisting and untwisting with decreasing amplitude until the internal friction of the shaft gradually brings it to rest. If a series of such impulses is applied at a frequency corresponding to the natural frequency of the shaft, a condition of synchronous

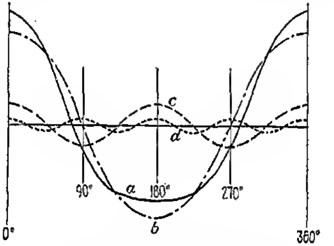

FIG. 18.—Inertia forces causing vibration.

torsional vibration is established and, unless the energy input is absorbed by damping in some way, the shaft will eventually fail.

This condition will exist whenever the natural frequency of the shaft divided by the engine speed is a whole number or a half number for the four-cycle engine and a whole number for the two-cycle engine. Accordingly, an engine may have more than one critical speed, yet may operate very smoothly at all other speeds. By methods of analysis (see p. 1437) the natural frequency of the mass elastic system of a given engine, and the relative locations of the applied forces and the forces resisting oscillation, can be calculated. In this way it can be determined whether the critical speeds of the engine lie within the range of speeds at which it will normally operate. If they do, the natural frequency of the shaft may be changed by increasing the diameter of the shaft, decreasing the weight of the flywheel, or shortening the shaft.

If a critical speed remains after all possible changes have been made, the tachometer for indicating engine speed should be marked with a red line at the critical speed and operation at this speed avoided.

A method of controlling torsional vibration which is coming into general use utilizes a vibration damper on the shaft to absorb the energy of vibration

in large ships where the power required by auxiliaries is large, it would require extra power to be built into the main engine.

There is a growing tendency in small vessels to include the water and oil pumps in the engine structure and drive them by means of gearing from the crankshaft. When the generator is also engine-driven, chains or V-belts are utilized for the drive. When this is done, stand-by auxiliaries driven from an independent source of power are provided.

An arrangement that has been practically standardized in tug practice is to have a diesel-driven generator and a complete set of motor-driven auxiliaries in addition to the built-in equipment of the main engine. When getting under way or during maneuvers that require starting and stopping of the main engine over a considerable time, the diesel generator is kept running to operate the starting air compressor, steering engine, electric lights, etc. After the engine is started and during subsequent maneuvering, water and oil circulation are taken care of by the attached pumps and, after the boat is in the fairway, the electrical load is shifted to the attached generator and the diesel generator is shut down.

In some cases occasionally used auxiliaries, such as the bilge pump and fire pump which require considerable power, are connected by chain drives to the intermediate or propeller shaft, with clutches interposed, so that they may be operated whenever desired merely by engaging the clutches. Where there are several of these units, they may be driven from a jackshaft, each with a separate chain drive and a single chain used to drive the jackshaft.

Battery Systems. Auxiliary arrangements such as have been described for smaller vessels, in which a generator driven from the main engine is used, generally include a storage battery, with "floating system" connections. The battery comprises enough cells to give the same voltage as the generator and is connected across the main power bus. If the engine is stopped or is slowed down enough to reduce the generator voltage below normal, current from the battery flows into the line and the battery takes the load. When the engine is speeded up to the point where the generator voltage is again normal, the generator again takes the load and current flow back into the battery to bring it up to a normal state of charge. Also, the battery helps to carry the load if a sudden, short demand is made for power beyond the capacity of the generator.

Although attached generators are designed to have a flat voltage characteristic over a fairly wide range of speed, it is customary to provide a voltage regulator, usually of the carbon-pile type, in connection with such generators. This regulator acts to maintain a constant voltage whenever the engine is operated at varying speeds.

FUELS

Although under special circumstances diesel engines have been operated with a variety of fuels, normal operation requires the use of a fuel refined from crude petroleum and obtained after the gasoline, kerosene, and other light products are removed from the crude. Wide variations in the quality of fuel are found, but in general the small, high-speed engines are confined to the use of lighter oil of comparatively high gravity, while the large engines that have greater combustion-chamber volume, more time for combustion, and a smaller ratio of exposed-surface-to-air volume in the combustion chamber can burn oils of low gravities, corresponding to the oil burned under

by friction. In one form it comprises a flywheel held between friction disks. When the angular velocity of the shaft decreases or reverses, the flywheel continues to move at the original velocity and the friction dampens the vibration. Another form uses hydraulic friction as the damping force, and a third utilizes spring-controlled rotating weights. Any change in velocity causes the radius of rotation of the weights to change, thus varying the moment of inertia and causing the natural frequency of the shaft to change.

Resilient Mounting. After all vibration that might be harmful to the engine has been removed or neutralized, there will always be a certain amount of residual vibration which, although harmless to the engine structure, may sometimes cause unpleasant vibration in the vessel's hull or superstructure, or rattling of pipes and small parts. A method in common use for eliminating these effects is applicable to auxiliary engines or generator sets used for electric drive but has not as yet had any extensive application to propulsion engines. It uses resilient mounting under the engine so that vibration will be confined to the engine and will not be transmitted through the foundation to the hull.

Rubber mountings, arranged so that there is no metal-to-metal contact between the foundation and the engine bed, or holding-down bolts, have been used successfully with small engines. Similar mountings of cork have been used. The most effective isolation of vibration is obtained with steel-spring mountings. These are made up in the form of complete units that are inserted under the bedplate in place of the usual chocks and arranged so that the tension of the springs can be adjusted to suit the particular engine conditions. In its latest form this type of mounting is designed to prevent dislocation of the engine by shock resulting from gunfire, bombs, etc.

The application of resilient mounting to propulsion engines must take account of the fact that the engine is connected to a rigidly restrained propeller shaft. Also the engine is heavy and its center of gravity relatively high, resulting in an overturning moment when the vessel rolls in a seaway. In the few installations that have been made in connection with propulsion engines a flexible coupling is inserted between the crankshaft and propeller shaft to allow freedom of movement in excess of any movement of the engine and the engine bed is chocked fore and aft to prevent end movement.

Complete isolation of engine vibration requires that no rigid pipe connection be made to the engine. All piping for oil or water should be connected by means of flexible metal or rubber tubing. In addition to the flexible metal connection between the exhaust manifold and muffler, the muffler should also be resiliently mounted.

Noise Suppression. Since sound is the result of air waves produced by vibration, the matter of noise suppression should be considered in connection with vibration. From the first inception of the diesel engine the need for silencing or muffling the sound of the exhaust has been recognized. Early hit-or-miss methods have been succeeded in later years by development of exhaust silencers based on scientific study of the action of sound waves.

It has been found that the most effective damping of exhaust noise is obtained by varying the cross sections of the channels through which the gases flow. This has led to various designs of silencers, which are divided into separate chambers in which the desired change of cross section is obtained by perforated pipes, pipes with several branches, or partitions with holes for the gas passage. Effective silencing can be produced by throttling, whereby the pressure is converted to kinetic energy, after which the kinetic

steam boilers. Certain characteristics of fuel oil that have a relation to its value for use in diesel engines may be briefly explained as follows:

Gravity. The gravity of an oil is expressed as specific gravity, Baumé gravity, or A.P.I. gravity. The last has been established as a standard of the American Petroleum Institute and is now the most widely used in American diesel-engine practice. It is expressed in degrees, as determined by the following formula:

$$\text{Deg A.P.I. 60 F} = \frac{141.5}{\text{specific gravity at 60 F}} - 131.5$$

By this formula the gravity of water is 10, that of liquids heavier than water is less than 10, and that of liquids lighter than water is more than 10. *Although gravity of itself is not an index to the quality of the oil, it serves* as an indicator of the suitability of an oil for use as diesel fuel. In general, the higher the A.P.I. gravity, the less trouble will be experienced in burning the oil.

Heat Content. The heat content of an oil, which determines the amount of work that may be obtained from it, is expressed as the number of Btu per pound, as determined by burning a sample in a calorimeter and measuring the heat liberated. Since this measurement includes the latent heat that is released by condensation of the vapor formed by the combustion of the hydrogen in the oil, it represents some heat that can never be utilized in a working engine, because the gas resulting from combustion leaves the cylinder at a temperature far above the condensation temperature (see p. 366).

Flash Point. The temperature of the oil at which an open flame applied near the surface of the oil will cause the vapor from the oil to ignite is the flash point. Although it has no relation to the performance of the fuel in the engine, it is important in relation to safety in handling, storing, and transporting. In general a flash point of 150 F or more indicates that the oil is a safe one.

Pour Point. Another characteristic that is of importance in connection with the handling and storing the oil is its pour point, the lowest temperature at which it will flow. For marine use, a pour point of 15 F is satisfactory.

Viscosity. The fluidity of an oil, in terms of viscosity, has an important relation to its suitability for pumping and atomization. There are several different kinds of viscosimeters in use, with correspondingly different scales, but the one most widely used in the United States is the Standard Saybolt Universal, known as the SSU. The viscosity of an oil can be reduced by heating, but the temperature required to produce a given viscosity will vary with oils of different origins. In general it may be said that any oil fluid enough to be handled by the injection pump will atomize sufficiently at the injection nozzle, and any oil with a viscosity of 200 SSU will meet this requirement. If the viscosity is higher than this, the oil must be heated to a temperature which will reduce the viscosity to 200 SSU.

Carbon Content. At one time the carbon content of an oil was considered a highly important factor in relation to the combustion characteristics. As determined by the Conradson method, it is the percentage by weight of carbon remaining after a sample of the oil has been evaporated over a burner. It will vary from 0.5 to 10 percent in different oils. At present there is considerable difference of opinion as to the influence of carbon

energy is converted into heat by turbulence and internal friction, but this results in loss of engine output if appreciable back pressure is produced. One way in which this principle may be applied effectively is by the use of an exhaust turbine. The turbine acts as a throttle that produces power and also dampens the noise without producing harmful back pressure.

The annoyance caused by sparks issuing with the exhaust gases, as well as the danger in the case of vessels carrying inflammable cargo or working around oil docks, etc., led to the development of spark-arresting exhaust silencers. The use of water in the silencer for quenching is undesirable, and the method commonly used in modern silencers is to utilize centrifugal force to extract the spark-creating solids from the exhaust gas. The gas passage is arranged to give the gas stream a whirling motion, thus causing the solids to be thrown out and caught in a collector, from where they may be removed at intervals.

The principles of exhaust-gas silencing have been extended to apply to the air inlet on the four-cycle engine and the scavenging pump inlet on the two-cycle. This is particularly desirable in the case of high-speed two-cycle engines using rotary blowers with high-intake velocities. The general principles of noise suppression in the exhaust gases apply here with certain structural differences due to the tonal differences in the exhaust gas and inflowing air.

In considering the noises originating in the moving parts of an engine, it may be stated as a generalization that as engine speeds become higher such noise increases and its tonal quality becomes more annoying. With the modern trend toward high speeds the matter of general noise suppression must be given increasing attention. In such special installations as submarine boat machinery it has become a matter of major importance because of its mental and physical effects on personnel. Much progress has been made in the direction of sound absorption and elimination of sound reflections from bulkheads and other resonant surfaces.

Indicative of the methods used in suppressing noise by insulation is the procedure that proved effective in the case of a large, seagoing tug. The main engine is mounted on Micarta blocks instead of steel chocks; the auxiliary generator sets are mounted on spring-type dampers and each is enclosed in an acoustic cabinet; the bulkheads, ceiling, and gratings are sheathed with acoustic paneling; the undersides of engine-room ladder treads and floor plates are lined with insulating material; and the feet of the ladders rest on rubber pads. The result in this case is the elimination of resonance and reflected noise. The engine noises have a flat tone, and the absence of magnification permits conversation in the engine room in normal tones without effort.

MANUFACTURERS' STANDARDS

The conditions under which marine diesel engines operate vary widely and there are many factors that have a bearing on types and sizes of accessory equipment; also there are many optional variables that enter into the design of such engines. For these reasons it is not possible to set up rigid standards that will apply to all installations. A limited amount of standardization has been adopted by the engine builders who are members of the Diesel Engine Manufacturers Association. Some of the standards are presented here in brief form, to indicate their nature and are not necessarily presented in the exact language of the code of the association.

on combustion, but the Conradson carbon content is always included in fuel-oil specifications. As a generalization it may be stated that for satisfactory operation the smaller the engine the smaller should be the Conradson carbon content.

Sulfur. The bad effects of sulfur in the fuel were considered in earlier days important enough to require the sulfur content to be held to a fraction of 1 percent, but it is now recognized that little harm can come from it. About the only way in which it can be harmful is by the sulfur dioxide formed during combustion combining with the water in the exhaust gas, if the latter falls below the condensation temperature, attacking the metal of the exhaust lines and muffler. Recent experiments, to be mentioned in another section, indicate that there may be a relation between sulfur content and rate of cylinder liner wear. The sulfur content of present-day fuel may vary from 0.5 to 4 percent.

Water and Sediment. The water and sediment content, sometimes expressed as BS&W, for bottom sediment and water, is likely to be highly variable because an oil that leaves the refinery entirely free from water and sediment is subject to contamination in shipping and handling. A considerable amount of water may be harmless if it is dispersed throughout the fuel, but if it enters the fuel system in slugs it may cause misfiring. Sediment is harmful to the injection pumps and nozzles. Fuel specifications usually require the BS&W to be less than 1 percent, but in view of the ever-present possibility of contamination, all fuel should be filtered or centrifuged before being used in the engine.

Ignition Lag. The injection process that occurs after the fuel is injected takes place in four stages, as follows: ignition lag, ignition and combustion, controlled combustion during the injection period, and afterburning. The most important phase is ignition lag, which is the time that elapses between the start of injection and the ignition of the first particles of fuel; by measuring it, the so-called **ignition quality** of the fuel is determined.

If the ignition lag is too great, injection is completed before the initial ignition occurs; when it does occur, the whole charge of fuel is inflamed, so that combustion occurs with explosive violence, the engine knocks, the exhaust is smoky, and carbon is deposited in the cylinders. On the other hand, if the lag is too short, it lengthens the time of combustion, causes increased heat losses to cooling water and exhaust, and prevents thorough mixing of fuel and air. These things are of prime importance with high-speed small-bore engines but of less importance with large, slow-speed engines.

Ignition quality is expressed in several ways, the simplest of which is the diesel index; the expression for which is

$$\text{Diesel index} = \frac{\text{aniline number} \times \text{A.P.I. gravity}}{100}$$

The aniline number is the lowest temperature at which freshly distilled aniline will mix with the oil to be tested. The mixture is heated until the solution is clear, then allowed to cool. The temperature at which it becomes turbid is the aniline number. The diesel index does not give a very accurate indication of the ignition quality of oils from mixed crudes.

A more accurate method of expressing ignition quality is by cetane number, obtained by comparing the fuel with a standard reference fuel composed of

Ratings. The standard rating is the net brake horsepower that the engine will deliver continuously with atmospheric temperature not over 90 F, and barometric pressure not less than 29 in. Hg. The rating must be such that the engine will operate on the test stand with an overload of 10 percent for 2 hr, consecutively.

Brake Mean Pressure. Because of the many variables in engine design and construction, no standard can be established for bmep that would have general application.

Net Brake Horsepower. The standard net brake horsepower is measured by a dynamometer at the engine coupling, without correction for power required by auxiliaries which may or may not be driven by the engine. When comparing proposals the buyer should consider any variations in attached auxiliaries in their relation to power, fuel consumption, weight, and additional auxiliary power required.

Horsepower and Fuel-consumption Guarantee. Precise determination of power output after installation in a vessel is rarely possible. For this reason tests for fulfillment of horsepower and fuel consumption guarantees are limited to the engine builder's test stand. Fuel-consumption guarantees are made in terms of fractions of a pound per net brake horsepower per hour at rated power and speed. Such guarantees are based on fuel having a high heat value of 19,350 Btu per lb.

For nonsupercharged engines the power and fuel consumption guarantees are contingent on the following conditions:

1. Intake air temperature between 40 and 90 F.
2. Barometric pressure of intake air between 29 and 30 in. Hg.
3. Fuel oil to conform to manufacturer's specifications for the type of engine under test.

All fuel-consumption guarantees are subject to a tolerance of 5 percent, owing to variations of intake-air density caused by atmospheric temperature and barometric pressure, and to variations in low-heat value of fuels having the same high-heat value. Fuel-consumption guarantees are not made at other than rated speeds and load except for constant-speed engines for electric drive. The association has not yet established a basis for fuel-consumption guarantees for supercharged engines.

Critical Speeds. *Although reasonably accurate predetermination of* critical speeds can be made as far as the entire propulsion assembly as a rotating system is concerned, the uncertainties of propeller and water flow to propeller make it impracticable to guarantee the exact location and amplitude of torsional vibration.

Equipment. To suit the variable requirements of different types of engines the association has established a minimum list of equipment to be supplied with every marine engine with certain additions to be applied according to whether the engine is (1) reverse-geared, (2) direct-connected, reversible, (3) reduction-geared, direct reversible, or (4) the main engine for electric drive or the auxiliary engine for electric power.

Additional equipment is supplied as required by the purchaser.

Spare Parts. Most ships are classified with one or more of the classification societies, and the spare parts supplied with engines for such ships conform to the societies' requirements. For unclassified vessels it is standard practice of the association to furnish certain minimum spares, which are specified with the bid.

cetane and alpha-methyl-naphthalene. The former ignites very easily and is given an arbitrary scale number of 100, while the latter is very hard to ignite and is given a rating of zero. The procedure is to determine in a special test engine, known as the CFR engine, the angle of crankshaft rotation between the time injection begins and the time ignition occurs, when the fuel being tested is injected. The standard reference fuel is then tested until a mixture of cetane and alpha-methyl-naphthalene is found, the delay angle of which will be the same as that of the test fuel. The percentage of cetane in this mixture will then be the cetane number of the fuel tested.

Ash. The solid matter remaining after a sample of the fuel has been burned in a test dish is called ash and is expressed as a percentage by weight of the fuel burned. In general it includes the abrasive impurities that may cause scoring of the liners and rings and should be as low as possible, the usual figure being 0.1 percent.

Fuel Classification. Some years ago it was thought that a specification could be developed that would produce a single fuel suitable for all diesel engines. Subsequent extensive research definitely established the fact that no one standard fuel can be suitable for all engines. The only way in which standardization can be accomplished is by providing several different fuels on the basis of high-speed, medium-speed, and slow-speed engines. Research work to date is by no means conclusive but the American Society for Testing Materials has established a tentative classification of fuel oils as shown in Table 2.

Table 2. A.S.T.M. Proposed Diesel Fuel Classification

Characteristic	Grade				
	1-D	3-D	4-D	5-D	6-D
Flash point, deg F, min[a]	115 or legal	150	150	150	150
Water and sediment, % by volume, max	0.05	0.1	0.6	1.0	2.0
Viscosity, SSU at 100 F	Min[b] 32 Max 50	32 70	 250		
Viscosity, SSU at 122 F, max	......	......	......	100	300
Carbon residue, % by wt, max	0.2	0.5	3.0	6.0	
Ash, % by wt, max	0.02	0.02	0.04	0.08	
Pour point, deg F, max[c]	35	35	35		
Sulfur, % by weight, max[d]	1.5	1.5	2.0	2.0	
Cetane no., min	50	40	30		
Diesel index, min	45	30	20		
Viscosity-gravity No., max	0.86	0.89	0.91		
Boiling point-gravity No; max	188	195	200		

[a] As stated or as required by local fire regulations, Underwriters, or state laws.
[b] For viscosities below 35 SSU at 100 F, other methods may be used and results converted.
[c] Lower pour points may be specified when required by local conditions, though less than 0 F should not be necessary.
[d] Not ordinarily of consequence as regards combustion.

Fuel-oil Tables. The values given in the tables that follow should be considered as approximations only, but they are close enough to the true values to serve as a guide to the general relation between the properties of any given oil that may be encountered in service.

Wrenches and Tools. All necessary special tools and wrenches that cannot be purchased readily in the open market are supplied as standard engine equipment, but no duplication of tools is made for two or more engines in the same engine room. *Other* tools and wrenches of commercial types may be supplied by agreement between buyer and seller.

Engine Classification. It is the general practice of members of the association to construct all engines to comply with the rules of Lloyd's and the American Bureau of Shipping, but inspection and certification by the societies are optional with the purchaser and at his own expense.

Fuel Specifications. *Members of the association will recommend some* one of the A.S.T.M. grades of diesel fuel (tabulated in a preceding section) for each of their engines and favor the buying of fuel by A.S.T.M. designation.

Foundations. Foundations are not a part of the engine or inclusive in the engine contract, but the engine manufacturers will cooperate with naval architects and shipbuilders by suggesting changes of design that may be helpful in obtaining suitable foundations.

Torsional Calculations. Members of the association assume responsibility for the accuracy of torsional vibration data and calculation of critical speeds, but they have no control over the hydraulic conditions under which the propellers will operate. Hence they cannot guarantee final results.

DESIGN CONSIDERATIONS

Since several factors, such as number of cylinders, bore and stroke, mep, and piston speed, must be taken into account when designing a diesel engine and their relation is such that any change in one causes a changes in one or more of the others, it is customary to choose one of these factors as the basis for the design and adjust the others to suit. A commonly used starting point for design is the selection of the piston speed desired.

Piston Speed. In the early days of diesel-engine design piston speed, expressed in feet per minute by multiplying the rpm by twice the piston stroke in feet, usually fell within the range 600 to 700 fpm. In succeeding years there has been a continued increase in piston speed so that some engines built today have a piston speed of 2,000 fpm. The divergence of opinion among designers in regard to piston speed is shown by Table 6 which is the result

Table 6. *Variation of Piston Speed and Piston Stroke*

Stroke range, in.	Piston speed range, fpm	No. of engines checked
	Four-cycle engines	
4–10	600–2,000	80
10–15	660–1,800	48
15–20	600–1,550	38
20–32	900–1,200	19
	Two-cycle engines	
4–10	600–1,670	9
10–15	600–1,440	14
15–20	735–1,000	8
20–36	1,000–1,275	7

$f(x) = 0$, where $f(x)$ means any function of x, and plot the curve $y = f(x)$ for a sufficient number of values of x to obtain a general idea of the shape of the curve. Then pick out the regions in which the curve appears to cross the axis of x, and plot the curve more accurately in each of these regions. Thus, by successive approximations, plotting the important parts of the curve on a larger and larger scale, determine as accurately as necessary the points where the curve crosses the axis—that is, the values of x which make $f(x)$ equal to zero.

Thus, suppose that $f(x) = 3.0$ when $x = 2.6$ and -5.0 when $x = 2.7$ (see Fig. 1). Then the curve must cross the axis somewhere between $x = 2.6$ and $x = 2.7$; and since it will not vary greatly from a straight line between those points, it is seen that it must

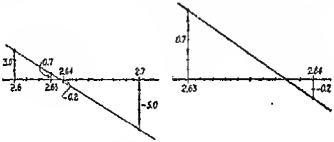

FIG. 1.

cross near 2.64. Suppose the value of $f(x)$ when computed for $x = 2.64$, is -0.2, and when computed for $x = 2.63$ is $+0.7$; then the root lies between $x = 2.63$ and 2.64. Plotting this section on the larger scale, it is seen that the next guess should be about 2.638; and so on.

Instead of writing the original equation with all the terms on the left-hand side, it is often better to divide the expression into two parts, say $f_1(x)$ and $f_2(x)$, writing the equation in the form $f_1(x) = f_2(x)$. If then the two curves $y_1 = f_1(x)$ and $y_2 = f_2(x)$ be plotted separately, on the same diagram, the value of x corresponding to their point of intersection will be the desired root.

SOLUTION OF SIMULTANEOUS EQUATIONS

The Meaning of a System of Simultaneous Equations. To solve a system of n simultaneous equations in n unknowns, means to find all the sets of values of the unknowns (if any) which, when substituted in the given equations, will satisfy all the equations at the same time. If a system of equations has no solution, the equations are "inconsistent"; if it has an infinite number of solutions, the equations are "not all independent."

Simultaneous Equations of the First Degree in Two Unknowns.

$$\begin{array}{l|c|c|}
 & \multicolumn{2}{c}{\text{Factors}} \\
(1)\ a_1x + b_1y = c_1 & b_2 & -a_2 \\
(2)\ a_2x + b_2y = c_2 & -b_1 & a_1 \\
\hline
\end{array}$$

$$(a_1b_2 - a_2b_1)x = b_2c_1 - b_1c_2 \qquad \therefore x = (b_2c_1 - b_1c_2)/(a_1b_2 - a_2b_1)$$
$$(a_1b_2 - a_2b_1)y = a_1c_2 - a_2c_1 \qquad \therefore y = (a_1c_2 - a_2c_1)/(a_1b_2 - a_2b_1)$$

Here (1) is multiplied by b_2, (2) by $-b_1$, and the products added so as to eliminate y; again, (1) is multiplied by $-a_2$, (2) by a_1, and the products added so as to eliminate x. (The process is most conveniently performed as follows: Write the multipliers, as b_2 and $-b_1$, at the right of the equations; multiply the first term of each equation by its proper multiplier and add; then multiply the second term of each equation by its proper multiplier, and add; and so on. This is simpler than the common practice of multiplying out each equation separately before adding.) If $a_1b_2 - a_2b_1 = 0$, the equations have no solution when $c_1 \neq c_2$, and an infinite number of solutions when

$c_1 = c_2$. The following **special solution** is possible when the sum and difference of the two unknowns are given:

$$\begin{array}{lll} & \text{Let } x + y = m & (1) \\ & \text{and } x - y = n & (2) \\ (1) + (2): & 2x = m + n & \therefore x = \tfrac{1}{2}(m + n) \\ (1) - (2): & 2y = m - n & \therefore y = \tfrac{1}{2}(m - n) \end{array}$$

Simultaneous Equations of the Second Degree in Two Unknowns.
(a) When the product of the unknowns, and their sum or difference, are given:

	$x + y = 5$ (1)	$x - y = 3$ (1)
	$xy = 4$ (2)	$xy = 4$ (2)
Squaring (1),	$x^2 + 2xy + y^2 = 25$	$x^2 - 2xy + y^2 = 9$
From (2),	$-4xy = -16$	$4xy = 16$
Adding,	$x^2 - 2xy + y^2 = 9$	$x^2 + 2xy + y^2 = 25$
Hence,	$x - y = 3$ or -3	$x + y = 5$ or -5
But	$x + y = 5$ or 5	$x - y = 3$ or 3
Therefore	$\begin{array}{c} x = 4 \\ y = 1 \end{array}$ or $\begin{array}{c} x = 1 \\ y = 4 \end{array}$	$\begin{array}{c} x = 4 \\ y = 1 \end{array}$ or $\begin{array}{c} x = -1 \\ y = -4 \end{array}$

(b) When the product and the sum of the squares are given:

$$\begin{array}{lrl} & xy = 5 \ (1) & \sqrt{(4)}: x + y = 6 \text{ or } \ 6 \text{ or } -6 \text{ or } -6 \\ & x^2 + y^2 = 26 \ (2) & \sqrt{(5)}: x - y = 4 \text{ or } -4 \text{ or } \ 4 \text{ or } -4 \\ \text{From (1),} & 2xy = 10 \ (3) & \begin{array}{l} \therefore x = 5 \\ \therefore y = 1 \end{array} \text{ or } \begin{array}{r} 1 \\ 5 \end{array} \text{ or } \begin{array}{r} -1 \\ -5 \end{array} \text{ or } \begin{array}{r} -5 \\ -1 \end{array} \\ (2)+(3): & x^2 + 2xy + y^2 = 36 \ (4) & \\ (2)-(3): & x^2 - 2xy + y^2 = 16 \ (5) & \end{array}$$

(c) When the sum or difference, and the sum of the squares, are given:

	$x + y = 5$ (1)		$x - y = 3$ (1)
	$x^2 + y^2 = 17$ (2)		$x^2 + y^2 = 17$ (2)
$(1)^2$:	$x^2 + 2xy + y^2 = 25$	$(1)^2$:	$x^2 - 2xy + y^2 = 9$
(2) :	$x^2 + y^2 = 17$	(2) :	$x^2 + y^2 = 17$
$(1)^2 - (2)$:	$2xy = 8$	$(1)^2 - (2)$:	$-2xy = -8$
	$xy = 4$		$xy = 4$
Then proceed as in case (*a*), above.		Then proceed as in case (*a*), above.	

(d) When one equation is of the first degree and the other of the second, as $ax + by = c$, and $Ax^2 + Bxy + Cy^2 + Dx + Ey + F = 0$: Solve the first equation for y in terms of x, and substitute in the second. This will give a quadratic equation in x. Solve this quadratic for the two values of x, and for each of these values of x find the corresponding value of y by substituting in the equation of the first degree.

Simultaneous Equations of the First Degree in n Unknowns. For example:

		Factors		
(*a*)	$2x - y + 3z + 5w = 29$	3	1	2
(*b*)	$5x + 2y - 2z + 3w = 15$	-5		
(*c*)	$3x - 4y + 7z - w = 12$		5	
(*d*)	$4x + 3y - 5z + 2w = 3$			-5
(*e*)	$-19x - 13y + 19z = 12$	-2	-31	
(*f*)	$17x - 21y + 38z = 89$	1		
(*g*)	$-16x - 17y + 31z = 43$		19	
(*h*)	$55x + 5y = 65$	16		
(*i*)	$285x + 80y = 445$	-1		

of a check of 185 different makes of engines. This table shows the range of speeds over different ranges of stroke. It is interesting to note that, as the stroke becomes greater, the range of piston speeds becomes less, also the range of piston speeds of two-cycle engines is narrower than that of four-cycle. The tabulated values were obtained from existing engines but there is no reason to assume that future development will not produce higher speeds.

Importance of Piston Speed. The principal reason for the heretofore general acceptance of piston speed as the basis of design is that the rate of wear of liners and piston rings is directly proportional to it although some authorities claim that other factors may be of greater importance. This takes no account of the influence of rotational speed on inertia and centrifugal forces, the two factors that have an influence on the stresses set up in the engine, the balancing, and noise in operation.

The formula for inertia force of reciprocation parts is (see p. 855)

$$F = 0.0000284N^2Wr(\cos a + C \cos 2a)$$

where N = rpm
W = weight of reciprocating parts
r = crank radius, in.

$$C = \frac{r}{l}$$

l = length of connecting rod, in.
a = crank angle

The formula for centrifugal force due to rotating parts is

$$F = \frac{WV^2}{gR}$$

where W = weight of two-thirds of connecting rod
V = velocity of crankpin
g = acceleration due to gravity
r = radius of crank, in.

It may be seen that the velocity of the crankpin enters into inertia and centrifugal forces; thus the rate of rotation is an important factor.

Piston speed alone takes no account of the variations in rates of rotation in different engines since a long-stroke engine turning at slow speed may have the same piston speed as a short-stroke engine turning at high speed. It appears then that rpm is not a satisfactory basis on which to rate an engine as high-speed or slow-speed.

A more definite classification of engines as low-, medium-, and high-speed on the basis of both rotative speed and piston speed is proposed by Prof. V. L. Maleev, who suggests a speed characteristic, designated as C_s, which is

$$C_s = \frac{NC}{100{,}000}$$

where N = rpm
C = piston speed, fpm

Substituting in this formula the expression for piston speed $C = Nl/6$, in which l is the length of stroke in inches, it becomes

$$C_s = \frac{N^2l}{600{,}000}$$

M_t is no longer nearly constant. In order to determine the resisting or stability moment at a specific large angle of inclination, the problem becomes one of determining the shift of the center of buoyancy and the measurement of the normal distance between F_b and F_w, the resisting or stability moment being the force couple.

It is to be noted that the stability moment at small angles is dependent upon the value of I_t, V, and the location of B and G, and that for large angles the stability moment is dependent upon the location of G and the magnitude of the shift of B. The shift of B is dependent directly upon the hull form.

By inspection of Fig. 2 it is apparent that the condition of positive stability requires that the point G be below the metacenter, M. In the event that the point G is above the metacenter, the tendency of the ship will be to roll to an angle of inclination at which equilibrium will result. Such is the condition of negative stability and, if it is sufficiently large, capsizing may result. In the event that the point G and the metacenter are coincident, a condition of indifference will result.

It is particularly pertinent to note that the presence of free liquid surface in the ship will cause a reduction in the $\overline{GM}$ or stability of the ship. It may be readily shown that the following relationship exists:

$$\overline{gm} = \frac{i}{V} p \tag{14}$$

where $\overline{gm}$ = reduction in $\overline{GM}$, ft
- i = moment of inertia, ft^4 of the free surface about a fore-and-aft-axis through its center of gravity
- V = displacement of the whole ship, cu ft
- p = ratio of the density of the free surface liquid to the sea water displaced by the ship

Therefore, the actual stability is $\overline{GM} - \overline{gm}$. Attention is invited to the seeming paradox that the reduction in stability, $\overline{gm}$, is wholly independent of the quantity of the free liquid.

Inclining Experiment. Calculation of the $\overline{GM}$ necessitates location of the center of gravity, G, of the ship. Its location by analytical means is a laborious program and, owing to the magnitude of the work, is apt to be in error. The location of the center of gravity may be easily determined relative to the metacenter by experiment. For small angles of inclination, the following relationship will directly determine the $\overline{GM}$:

$$\overline{GM} = \frac{M}{\tan\theta \times W} \tag{15}$$

where $\overline{GM}$ = metacentric height, ft
- M = a heeling moment, ft-tons
- θ = a small angle of heel, deg
- W = weight of ship, tons

The heeling moment, M, may be induced by moving a weight, w, athwartship a distance of d ft. The tan θ of Eq. (15) may be determined by use of a plumb-line pendulum. Letting l denote the length of the pendulum

Engines with the same C_s may be considered as having the same speed, regardless of variations in their rpm. Maleev classifies all engines with a characteristic below 3 as slow-speed, those with a characteristic between 3 and 9 as medium-speed, from 9 to 27 high-speed, and above 27 super high-speed.

It is interesting to note that there is no fixed relation between speed characteristic and stroke-bore ratio. About as many low-speed engines are found with a small stroke-bore ratio as there are high-speed engines with long stroke. In general the stroke-bore ratio of existing engines varies between 1.00 and 1.9, with an average value between 1.3 and 1.35.

Numbers of Cylinders. Most marine diesel engines are built with vertical in-line cylinders, with the V arrangement becoming more common where space and weight considerations are important. The number of cylinders will vary from 1 to 16, with the largest number found in the 6-cylinder group because of the better balance, as noted in a previous section. Since the weight of an engine per horsepower decreases as the number of cylinders is increased the 8-, 10-, 12-, and 16-cylinder arrangements are used where low specific weights are desirable. Also they offer a means of increasing the engine power without increasing the height and width.

General Procedure. Although a detailed analysis of the step-by-step procedure in designing a new engine cannot be presented here, the procedure can be outlined briefly. The starting point is the selection of the principal characteristics such as the speed characteristic previously explained, the stroke-bore ratio L/D, and the mep P. This latter value and the compression ratio R are sufficiently standardized in practice to permit their selection on the basis of previous experience, without calculation. The number of cylinders will be determined by the factors mentioned previously.

From Maleev's method of analysis, the basis of computation for determining the revolutions and cylinder diameter is the standard formula for horsepower, $hp = PLAN/33{,}000$, but to make it more workable it is modified by expressing L, A, and N in terms of D as $L/D = Q$. The revolutions will then be

$$N = 774.6\sqrt{\frac{C_s}{QD}}$$

and for the two-cycle single-acting cylinder

$$hp = 0.001534PD^{2.5}\sqrt{QC_s}$$

from which the cylinder diameter will be

$$D = \left(\frac{651.5\text{ hp}}{P\sqrt{QC_s}}\right)^{0.4}$$

For the four-cycle engine with half as many working strokes

$$D = \left(\frac{1{,}303\text{ hp}}{P\sqrt{QC_s}}\right)^{0.4}$$

Dimensions. After the principal characteristics have been determined, the dimensions of the various parts are calculated on the basis of a theoretical indicator diagram, from which the stresses due to gas pressure, pressure acting on the piston, inertia forces, etc., can be determined.

in feet and a denote the transverse movement of the pendulum, Eq. (15) may be expressed as follows:

$$\overline{GM} = \frac{w \times d}{\dfrac{a \times W}{l}} \tag{16}$$

The plumb line should be swung in a hatchway to afford maximum length. It is customary to dampen the action of the pendulum by immersing the plumb bob in a bucket of oil. Needless to say several plumb lines should be used and judiciously located forward and aft, the results averaged and checked. Care should be taken to perform the experiment under conditions of slackened mooring lines, calm water, and light winds in order to eliminate unknown errors. The condition of the ship should be carefully noted in regard to ullage of all tanks, foreign weights, and the $\overline{GM}$ should be corrected for free liquid surfaces in accordance with Eq. (14). It is to be remembered that the $\overline{GM}$ derived from the inclining experiment represents the stability at the time of the experiment and that any subsequent changes, additions, or removal of weights must be accounted for.

Effect of Shifting of Weights. A very useful principle, often used in stability calculations, for determining the **shift of the center of gravity** of a weight system is as follows: Assume the notation, w = weight shifted; W = total weight of the whole system; d = distance through which w has been moved; c.g. = center of gravity of the whole system.

$$\text{Shift of c.g.} = \frac{w \times d}{W} \tag{17}$$

The direction of the shift will be parallel to the movement of w.

Example. A weight of 80 tons is vertically raised 30 ft from the hold to the main deck of a ship of 10,000 tons displacement. The shift of center of gravity, in this case the rise of center of gravity, will be $\frac{80 \times 30}{10{,}000}$, or 0.24 ft. In event the weight is moved horizontally 20 ft, the center of gravity will shift horizontally aft $\frac{80 \times 20}{10{,}000}$, or 0.16 ft. This principle may be used for determining the shift of the center of gravity caused by adding additional weight by first assuming that the added weight is placed aboard the ship at the center of gravity of the ship, then assuming the weight is moved to its assigned location and calculating the shift of the center of gravity in a manner similar to the above example. The removal of a cargo weight may be handled likewise, but in reverse order.

Transverse Dynamic Stability. For any particular angle of heel the amount of work required to heel the ship to that angle is called the dynamic stability for the particular inclination. Thus the dynamic stability, at any angle θ, equals $\int_0^\theta D \times GZ\, d\theta$. In other words, the area under a **curve of stability or righting moments** plotted against an angle of heel of θ is the dynamic stability. Such a curve can be constructed and the area measured. The character of the curve of righting moments is usually such that the righting moment is proportional to the angle of heel up to an inclination

CONTENTS

whereby the deck edge becomes immersed. This angle of inclination is usually the inflection point of the curve. For ships of positive stability, the slope of the curve is positive to the inflection point.

Period of Roll. The period required for a ship to roll from the vertical to the port, returning past the vertical to the starboard, and thence returning to the vertical is termed the period of roll.

For angles of roll up to and approaching the inflection point of the curve of stability moments, and assuming simple harmonic oscillation, the period of roll may be determined with reasonable accuracy by the following formula:

$$T = \frac{1.108P}{\sqrt{\overline{GM}}} \tag{18}$$

where T = period as defined, sec

$\overline{GM}$ = transverse metacentric height, ft

P = radius of gyration, ft, of the mass of the ship about a fore-and-aft axis through its center of gravity. An average value of 0.4 times the beam may be used for most merchant vessels.

From an inspection of Eq. (18) it will be noted that an increase in $\overline{GM}$ will shorten and that an increase of P will lengthen the period of roll.

Forces Due to Dynamic Effect of Rolling. Rolling induces forces upon various parts of a ship due to the acceleration of the roll and the inertia effect of the mass of the various parts. The maximum velocity will occur at the vertical position and diminish to zero at the extremities of the roll. Therefore, the acceleration will be maximum at the extremities, and the maximum dynamic effect will occur at the maximum angle of roll. The tangential force may be determined as follows:

$$F = \left(\frac{W \times d}{46.7T^2}\right)\theta \tag{19}$$

where F = tangential force, lb

θ = maximum angle of roll, deg

T = period of complete roll, sec

W = weight of ship part being considered, lb

d = distance from the center of roll (see Center of Flotation, p. 1385) to center of gravity of the ship part

Longitudinal Stability. Analytically, the problem of longitudinal stability is similar to that for transverse stability except that the longitudinal metacentric radius is expressed by the following relationship:

$$\overline{BM}_L = \frac{I_L}{V} \tag{20}$$

where $\overline{BM}_L$ = longitudinal metacentric radius, ft (height of longitudinal metacenter above the center of buoyancy)

I_L = moment of inertia of the water plane of flotation about a transverse axis through the center of flotation

V = displacement of vessel, cu ft

BOWES DRIVE

Staff Contribution
Based on data from the Elliott Company

It is apparent that I_L will be considerably larger than I_T in the case of transverse stability. It follows that the longitudinal metacentric height, $\overline{GM}_L$, will be many times larger than the transverse metacentric height. The longitudinal metacentric height is of interest principally in determining changes in trim.

Trim. The difference between the draft at the bow and at the stern is termed the trim. **Change in trim** is simply the rotation of the ship about a transverse axis through the center of flotation whereby opposite changes in draft occur at the bow and the stern.

Movement, addition, or removal of weights forward or aft of the center of flotation will induce a change in trim in accordance with the following relationship:

$$\text{Change in trim} = \frac{L \times w \times a}{D \times \overline{GM}_L}\ \text{ft} \tag{21}$$

where L = length of water line, ft
w = weight shifted, tons
a = distance weight is shifted in a fore or aft movement, ft
D = displacement of ship, tons
$\overline{GM}_L$ = longitudinal metacentric height, ft

The **trimming moment** is equal to $w \times a$; therefore,

$$\text{Moment to trim 1 in.} = \frac{D \times \overline{GM}_L}{12 \times L} \quad \text{ft-tons} \tag{22}$$

and the total change in trim at bow and stern in inches is equal to the trimming moment divided by the moment to trim 1 in. Allocation of the change in draft at the bow and the stern is proportional about the center of flotation as follows:

$$\begin{matrix}\text{Change of draft}\\ \text{at stern}\end{matrix} = \left(\frac{\begin{matrix}\text{distance from}\\ \text{after perpendicular}\\ \text{to center of flotation}\end{matrix}}{\text{water line length}}\right) \times \text{change in trim} \tag{23}$$

$$\begin{matrix}\text{Change of draft}\\ \text{at bow}\end{matrix} = \left(\frac{\begin{matrix}\text{distance from}\\ \text{forward perpendicular}\\ \text{to center of flotation}\end{matrix}}{\text{water line length}}\right) \times \text{change in trim} \tag{24}$$

For changes in trim caused by the removal of weights, it is necessary to make an imaginary assumption that the weight is first moved over the center of flotation of the ship and the change in trim is calculated. Then assuming direct removal of the weight, the change of draft due to lightening of the ship may be directly calculated and the final draft ascertained. The effect of the addition of weights may be handled similarly in the reverse order.

NAVAL ARCHITECTURE

BY

E. BRYCE McCROHAN, Jr.

REFERENCES: Taylor, "Speed and Power of Ships," Ransdell, Inc., Rossell and Chapman, "Principles of Naval Architecture," Vol. II, Soc. Nav. Arch. and Mar. Engrs. Marks, "Mechanical Engineers' Handbook," McGraw-Hill. Sterling, "Marine Engineers' Handbook," McGraw-Hill. *Trans. Soc. Nav. Arch. and Mar. Engrs.*

GENERAL

The characteristics of the final completed design of a ship are the result of many compromises. A naval architect defines the character of a ship to suit many conflicting requirements. To be successful, it must be designed to suit the requirements of the service for which it is intended and must conform to the rules and regulations as applicable. The hull form and the dimensions of a ship are the primary characteristics upon which it is built. It is the duty of the naval architect to determine the primary characteristics of a ship and to coordinate them with the requirements of the marine engineer. The primary function of the marine engineer is to design and arrange the power plant of the ship and to coordinate the same to suit the overall requirements. It is the purpose of this section to provide the marine engineer with knowledge necessary to make preliminary estimates of hull characteristics.

It is necessary that the marine engineer be fully cognizant of the basic fundamentals that may influence the design and also be aware of the source of the data from which he must work. The character of the hull is of prime importance to his work.

The character and form of the hull are defined by the architect on the **line draft** plan, which is a graphical, geometrical representation of the hull form. It usually consists of three geometrical projections, as follows:

1. A **profile** or **sheer plan** which shows the outboard profile and the shape of the hull in elevation. The profile is usually constructed on a base line or base plane from which all dimensions are taken upward. Water planes are represented as water lines on the profile and are spaced at convenient and regular intervals parallel to the base line. Buttock lines are represented on the profile usually as curved lines and represent the trace on the hull surface of the intersection of planes parallel to the medial centerline of the ship, spaced at regular, convenient intervals, outboard and normal to the base plane.

2. The **half-breadth plan** indicates the shape and contour of half water planes in plan view as shown on the profile plan. The projections of the buttock lines are represented as straight lines spaced as stated above and parallel to the centerline plane. The vertical projection of the deck edge is also indicated.

3. The **body plan** consists of two half end-view transverse elevations. To the right hand is usually indicated the fore body viewed from the bow and to the left the after body viewed from the stern which represents the trace of transverse planes as they intersect the boundary of the hull form. The water

SHIP RESISTANCE AND POWERING

Water Resistance. The movement of a ship through the water is induced by the application of a driving force or thrust exerted upon it. In the case of steam or motor ships the driving force or thrust is supplied by mechanisms, such as screw propellers or paddle wheels, driven by the ship's propulsion machinery. The driving force in a sailing vessel is derived directly from the reaction of the wind force in the sails; in the case of towed barges, etc., the driving force is simply the towrope pull. In all cases the movement of the ship through the water creates various reactionary or retardant forces equal and opposite to the driving force. These reactionary or retardant water forces are termed **ship resistance** and may be expressed as follows:

$$R_t = R_f + R_r \tag{25}$$

where R_t = total bare-hull resistance, lb
R_f = frictional or skin resistance, lb
R_r = residual resistance, lb

These are described as follows:

1. **Frictional resistance** is the force required to overcome eddying water close about the wetted surface caused by the roughness of the surface and the ship's movement through the water.

2. **Residual resistance** is the difference between the total resistance and the frictional resistance and may be said to comprise the following:

a. **Wave-making resistance** or the absorption of energy resulting principally in the creation of wave systems set up in the water by the variations of the water pressure induced by the flow of water from bow to stern around and about the hull.

b. **Eddy-making, streamline or form resistance** resulting from the absorption of energy in setting up eddies of water at the after portion of the hull, owing to failure of the water to flow smoothly in streamline fashion about the hull. In most cases this resistance is relatively small for vessels of normal ship forms driven at ship speeds. It is usually neglected without serious error.

Frictional or Skin Resistance. The frictional resistance may be closely estimated by the following formula:

$$R_f = f \times A \times V^n \tag{26}$$

where R_f = frictional resistance, lb
f = a friction constant which varies with the length and roughness of the wetted surface
A = area of wetted surface, sq ft [Eq. (10)]
V = speed of vessel through the water, knots
n = an exponent

Froude established values of the friction constant for various lengths of hulls as given in Table 1 where the value of the exponent, $n = 1.825$. Thus for Froude's values of the friction constant, Eq. (26) is $R_f = f \times A \times V^{1.825}$.

Tideman established values of the friction constant and the exponent n of Eq. (26) for various lengths of hulls and characters of the wetted surface as given in Table 2.

planes are represented as parallel lines spaced as shown on the profile plan and parallel to the base plane. Similarly, the buttock lines are represented as vertical lines parallel to the centerline plane. Usually the deck edge is curved in both the half-breadth and profile plan and, therefore, shows as a curved line on the body plan.

The bounding surface of the hull form as shown on the line draft is defined as the molded form. Its dimensions are defined as molded dimensions.

PRINCIPAL DIMENSIONS OF THE HULL

The hull dimensions are as follows:

Length over-all is the length between the foremost to the aftermost part of the ship.

Length between perpendiculars is the distance between two vertical lines erected normal to the base plane. The forward perpendicular is located at the forward edge of the stem and passes through the designed water line at which the vessel is expected to float. The after perpendicular is usually located on single-screw vessels at the after edge of the rudder stock. On multiscrew vessels it usually passes through the after edge of the sternpost or the aftermost part of the designed water line. The location of the after perpendicular is subject to some variation, depending more or less on the type of the stern. For purposes of calculation it is a distinct advantage to locate the after perpendicular at the aftermost part of the designed water line.

Beam (molded) is the extreme breadth of the hull form as shown on the line draft.

Beam (extreme) is the extreme over-all breadth of the ship measured to the outside of the hull structure.

Depth (molded) is the vertical distance measured amidships, from the top of the keel plate to the top of the weather deck beams at the deck edge amidships.

Draft is the greatest vertical distance from the bottom of the keel to the water plane at which the ship is floating.

Displacement is the amount of water displaced by the immersed part of the vessel in either cubic dimensions of volume or the weight of the water so displaced. By Archimedes' principle the ship will displace a weight of water equal to the weight of the ship and everything on board. The density of sea water averages about 64 lb per cu ft (1 long ton, 2,240 lb, equals 35 cu ft); hence, the displacement in sea water is measured by the immersed volume at the water line divided by 35. In fresh water the corresponding divisor is usually taken as 36.

Tonnage is an arbitrary measure of the capacity of the entire enclosed portion of the ship including deckhouses and enclosures, assuming that 100 cu ft represents 1 ton. **Gross tonnage** refers to the total enclosed capacity, and **net tonnage** refers to enclosed capacity after deducting the space that is necessary to operate the ship, such as engine rooms, fuel, crew, and similar spaces. In general, net tonnage refers to the space available for earning capacity. Methods of measurement and taking of dimensions are defined by law and vary for the various maritime nations.

Hull Coefficients of Form. Assuming the following notation: L = length of water line, ft; B = beam, ft (usually molded beam); H = draft, ft; D = displacement in tons of sea water (2,240 lb per ton); V = volume of sea water displaced, cu ft; A = area of water plane, sq ft; M = area of amidship transverse section below the water line, sq ft, then

For fresh-water values of f, multiply by ratio 62.4/64.0

[a] From Taylor, "Speed and Power of Ships," Ransdell, Inc., and Rossell and Chapman, "Principles of Naval Architecture," Vol. II, Soc. of Nav. Arch. and Mar. Engrs.

$$C_b = \text{block coefficient of fineness} = \frac{V}{L \times B \times H} = \frac{35D}{L \times B \times H} \tag{1}$$

$$C_w = \text{water plane coefficient} = \frac{A}{L \times B} \tag{2}$$

$$C_m = \text{midship section coefficient} = \frac{M}{B \times H} \tag{3}$$

$$C_p = \text{longitudinal prismatic coefficient} = \frac{V}{M \times L} = \frac{35D}{M \times L} \tag{4}$$

$$C_q = \text{vertical prismatic coefficient} = \frac{V}{A \times H} = \frac{35D}{A \times H} \tag{5}$$

The following relationships exist between the hull coefficients of form:

$$C_p = \frac{C_b}{C_m}; \qquad C_q = \frac{C_b}{C_w} \qquad \frac{C_p}{C_q} = \frac{C_w}{C_m}; \qquad C_b = \sqrt{C_p \times C_q \times C_m \times C_w}$$

The values of hull coefficients that may be expected range about as follows:

	C_b	C_w	C_m	C_p	C_q
Freight steamers	0.65–0.80	0.75–0.85	0.85–0.95	0.75–0.85	0.80–0.95
Passenger liners	0.55–0.65	0.65–0.75	0.80–0.90	0.60–0.70	0.80–0.90
Battleships	0.60–0.65	0.70–0.75	0.85–0.92	0.65–0.70	0.80–0.90
Cruisers	0.50–0.55	0.60–0.65	0.80–0.90	0.55–0.60	0.75–0.85
Torpedo craft, yachts, etc.	0.35–0.55	0.55–0.60	0.75–0.85	0.50–0.60	0.65–0.80

Ratios. Various ratios of the dimensions of the immersed portion of the hull are used for comparative purposes and are as follows:

$$\text{Length-beam ratio} = \frac{L}{B} \tag{6}$$

$$\text{Length-draft ratio} = \frac{L}{H} \tag{7}$$

$$\text{Beam-draft ratio} = \frac{B}{H} \tag{8}$$

$$\text{Displacement—length ratio} = \frac{D}{\left(\frac{L}{100}\right)^3} \tag{9}$$

Curve of Sectional Areas. The curve of sectional areas is drawn to a convenient scale upon a base line as the abscissa equal in length to the water line and with the ordinates representing the cross-sectional areas of the immersed portion of the hull. The curve graphically represents the fore-and-aft distribution of the displacement. The shape of the curve has great influence on the resistance of the ship. The area under the curve to the base line represents the displacement V of the vessel, and the center of gravity represents the longitudinal position of the center of buoyancy (see p. 1385).

It is of interest to note that in some cases where barnacles and other marine growths increase the roughness of the wetted surface, the frictional resistance may be increased to values as much as 100 percent greater than that for smooth and clean bottoms. In extreme cases increases up to 300 percent have been noted.

Residual Resistance. Neglecting eddy and streamline resistance and assuming that the residual resistance is comprised principally of wave resistance, it may be said that the wave resistance of geometrically similar ships or models is proportional to their displacements when their speeds are proportional to the square root of their lengths. Such speeds are termed **corresponding speeds** and comparisons may be made when the ratio $V/\sqrt{L}$ (where V = speed, knots; L = length of water line, ft) of the ships or models being compared is the same. The ratio $V/\sqrt{L}$ is the speed-length ratio. The foregoing is known as **Froude's law of comparison** and is often expressed in many other ways.

"Geometrically similar" refers to ships or models whose underbodies have similar hull coefficients of form, dimension ratios, and whose hulls are geometrically similar with like curves of sectional areas.

Thus a system of estimating the residual resistance of a ship by comparison with that measured from existing ships or from the results of model tests is indicated by the law of comparison.

Methods of Estimating Resistance. By the use of the **frictional resistance** relationship and **Froude's law of comparison,** three methods are in common use for estimating the **total bare hull resistance** as follows:

1. *By Model Tests.* A reduced-scale model of the hull in question is constructed. The model is properly trimmed and ballasted to a draft as required, then towed at a proper **corresponding speed** in a ship-model testing tank and the **total resistance** is measured. Knowing the speed of the model, the area of the wetted surface, the frictional constant, and the exponent n of Eq. (26) from Tables 1 or 2, the frictional resistance of the model may be readily estimated. It is to be noted that the wetted surface of the model, when smoothed and in consideration of the scale, is closely similar to that of a clean and painted ship's wetted surface. By use of Eq. (25), the **residual resistance** of the model at a corresponding speed may be calculated. By the **law of comparison,** the residual resistance of the ship will be that of the model increased by the ratio of the displacement of the ship to the displacement of the model. For practical reasons, the water of testing tanks is usually fresh. Therefore, the ratio of displacements of ship to model must be multiplied by the ratio 64/62.4 (the ratio of densities of salt to fresh water). Again by the use of Eq. (26), the **frictional resistance** of the ship may be estimated. With the ship values of the residual and frictional resistance, Eq. (25) will give the **total bare-hull resistance.**

2. *Similar Ships.* Very often ships are designed by using an existing known hull of good repute as the parent or model and fashioning a new form from the known hull as a **parent design.** Where hulls are closely similar, excellent estimates of resistance may be made by using the parent hull as a model in a fashion similar to the method indicated for model tests in the preceding paragraph. Where vessels are dissimilar and the dissimilarity is such that its effect on the resistance may be estimated, very good results may be obtained.

3. *Taylor's Standard Series.* The late Rear Admiral D. W. Taylor, USN, by study of the results of many model tests made at the Washington Experi-

Wetted Surface. The area of the immersed portion of the hull in contact with the water is termed the wetted surface. Determination of this area is necessary in the estimation of the frictional or skin resistance. There are several more or less complex methods for estimating the wetted surface from the hull lines, expanded girths, etc., taken from the line draft. However, there are several simplified approximate methods for calculation. Taylor proposed the following formula which gives good results for ships of normal forms:

$$A = C\sqrt{D \times L} \tag{10}$$

where A = area of wetted surface, sq ft, of the hull proper not including appendages

D = displacement, tons 2,240 lb

L = length between perpendiculars or length of water line, ft

C = a coefficient dependent upon the beam-draft ratio, $\frac{B}{H}$ [Eq. (8)], and the midship section coefficient, C_m [Eq. (3)].

Taylor's contour curves of the coefficient may be selected from Fig. 1.

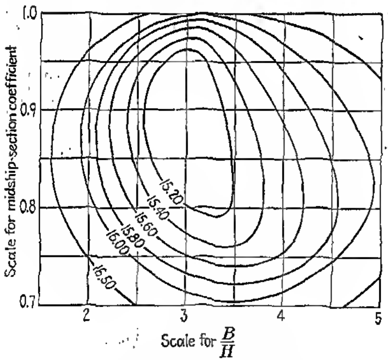

FIG. 1.—Taylor's contour curves.

For normal ship forms an average value for the coefficient of 15.6 is often satisfactory. Thus Eq. (10) is often represented as $A = 15.6\sqrt{D \cdot \times L}$. It is to be noted that the wetted surface of similar ships varies as the square of the ratio of their lengths.

Tons per Inch Immersion. The tons per inch of immersion is the weight in tons required to increase the draft by 1 in. and is expressed as follows:

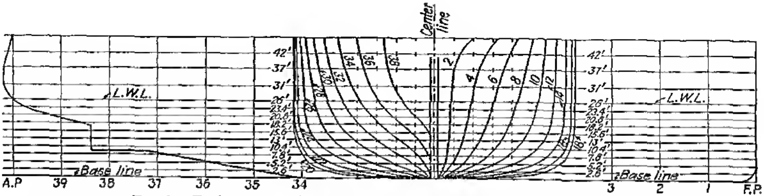

FIG. 3.—Taylor's parent-hull form—body plan and stem and stern profiles.

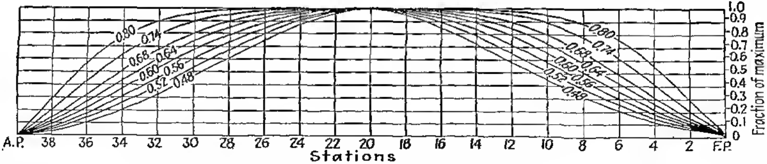

FIG. 4.—Taylor's parent-hull form—relative curves of section areas. Each curve has a corresponding longitudinal coefficient noted thereon.

$$\text{Tons per inch immersion} = \frac{\text{area of water plane}}{35 \times 12}, \quad \text{for salt water} \tag{11}$$

$$= \frac{\text{area of water plane}}{36 \times 12} \quad \text{for fresh water}$$

It is apparent that for vertical-sided hulls Eq. (11) will be exactly true and that for normal ships whose hulls are not wholly vertical sided, it will be closely true. In the latter case, the tons per inch of immersion will vary for each water line or depth of draft.

Center of Flotation. The **center of gravity** of the water plane at which the vessel is floating is the **center of flotation**. This is the **center of** rotation about which the ship rolls or pitches. **Rolling** is rotation about a fore-and-aft axis lying in the water plane. For small angles of roll it is assumed to be the fore-and-aft center line of the water plane (coincident with the centerline of the vessel). **Pitching** is rotation about a transverse axis through the center of gravity of the water plane whereby opposite changes in draft occur at the bow and stern.

Center of Buoyancy. The center of gravity of the displaced volume of the immersed portion of the hull is termed the center of buoyancy. The resultant force of all the upward buoyancy forces acts vertically through the center of buoyancy.

STABILITY

Archimedes' principle states, in part, that any buoyant body freely floating on the surface of a liquid will displace its own weight of the liquid. Assume that no external forces are applied to the body and that there are, therefore, only two forces acting: (1) The upward force of the water pressure distributed over the immersed portion of the body. (The resultant force of the summation of all buoyant forces will act upward through the center of gravity or the center of buoyancy of the displaced volume as the point of application.) (2) The weight of the body acting downward. (The resultant force of the summation of all the downward-weight forces will act downward through the center of gravity of the entire body as the point of application.)

When the body is floating in equilibrium, the two forces will act in the same vertical line and be equal in magnitude and opposite in direction. For any other condition, the body will tend to adjust its position on the surface of the liquid and seek such a position of equilibrium.

Similarly, the resultant upward-buoyancy force of the water upon a ship will act vertically upward through the center of buoyancy, and the total weight of the ship, including the weight of everything aboard, will act downward as a weight force and may be represented as a resultant force acting downward through the center of gravity of the whole ship. The condition for equilibrium requires that the weight force be equal and opposite to the force of buoyancy and lie in the same vertical line. In the event that the upward and downward forces are equal but do not lie in the same vertical line, the ship will adjust itself by changing its transverse and longitudinal position until equilibrium exists. For convenience, the problem of stability of a ship is resolved into transverse and longitudinal stability and analyzed separately as such.

Transverse Stability. Assuming that there is no change in the weight or the displacement of a ship and that a small angle of inclination, θ (from

mental Model Basin, evolved a parent hull form shown in Fig. 3 which had good resistance characteristics with hull proportions of proper stability and seagoing characteristics. A series of models were constructed with curves of areas as shown on Fig. 4 with prismatic coefficients [Eq. (4)] varying from 0.48 to 0.86 and with their displacement-length ratios [Eq. (9)] varying from 20 to 250. Two series of models were made with beam-draft ratios [Eq. (8)] of 2.25 and 3.75.

The models were towed in the testing tank at speeds giving **speed-length ratios** from 0.30 to 2.00. The **residual resistance** was calculated for these ratios. A family of curves of residual resistance in pounds per ton of displacement were drawn, with the prismatic coefficient as the abscissa and the displacement-length ratio as the ordinate, for each speed-length ratio. A series of charts were drawn for beam-draft ratios of 2.25 and 3.75.

In all cases the models had a common midship section coefficient [Eq. (3)] of 0.926. Taylor's experiments indicated that the midship coefficient could be varied between extremes of 0.70 to 1.10 with only minor variation in the residual resistance. The selection of a midship coefficient of 0.926 appeared to be the most economical, and the selection of the beam-draft ratios of 2.25 and 3.75 represented the extremes that were likely to occur in practice. Taylor also indicated that an increase in the beam-draft ratio from 2.25 to 3.75 made only a moderate increase in the resistance.

Where R_T = residual resistance, lb per ton of displacement; D = displacement tons, 2,240 lb; B = beam, ft; H = draft, ft; V = speed, knots; L = length of water line, ft; C_p = longitudinal prismatic coefficient.

[a] Condensed tables by Prof. K. S. M. Davidson from Rossell and Chapman, "Principles of Naval Architecture," vol. II, Soc. Nav. Arch. and Mar. Engrs.

0 to 5 or 10 deg) is induced by the application of an external overturning moment, M_o, it is readily discernible that the ship will roll from the normal water line, wl, to an inclined water line, w_1l_1, as shown in Fig. 2.

For small angles of θ, it may be assumed that the emerged wedge, W_1OW, will be similar to the immersed wedge, L_1OL and, since no change in displacement has been assumed, it may therefore be said that the axis of rotation will be about the point O (the fore-and-aft axis through the center of flotation). The center of buoyancy, B, will shift accordingly, to some point B_1. The resultant weight force, F_w, of the ship will act downward through the center of gravity, G, of the ship as the point of application, and the resultant upward-buoyancy force, F_b, will act vertically upward through the center of buoyancy, B_1, as the point of application. It is apparent that a force couple will result tending to resist the overturning moment, M_o. The value of this resisting couple equals $F_w \times \overline{GZ} = F_b \times \overline{GZ}$, where $\overline{GZ}$ is the normal distance between F_w and F_b. The distance $\overline{GZ}$ is termed the **righting lever.**

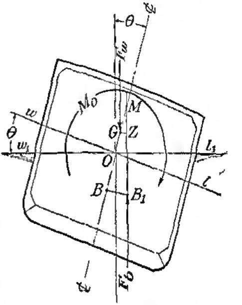

FIG. 2.—Transverse stability.

For small angles of θ the line of action of the force F_b will intersect the vertical centerline of the ship at a point M, which for small angles is very nearly constant. The point M is termed the **metacenter.** Letting $\overline{GM}$ denote the distance between the points M and G, it is apparent that $\overline{GZ} = \overline{GM} \sin \theta$ and that

$$\text{Resisting stability moment} = (\overline{GM} \times \sin \theta)F_b = (\overline{GM} \times \sin \theta)F_w. \quad (12)$$

For small angles $\overline{GM}$ is very nearly constant, and it is obvious that $\overline{GM}$ is, therefore, a measure of stability for such angles of inclination. $\overline{GM}$ is termed the **metacentric height** and, as such, is known as the stability of the ship.

The distance $\overline{BM}$ between the center of buoyancy, B, and the metacenter, M, is termed the **metacentric radius.** It can be easily proved that

$$\overline{BM} = \frac{I_t}{V} \quad (13)$$

where I_t denotes the moment of inertia of the water-line plane about a fore-and-aft axis passing through the center of flotation.

For angles of inclination larger than 5 or 10 deg, the line of action of the resultant buoyancy force, F_b, does not intersect the vertical centerline of the ship at a constant point. Therefore, for large angles of inclination the point,

This series of hulls constitutes the **Taylor Standard Series.** The complete data are available in his book, "The Speed and Power of Ships," and were intended to form a criterion and basis for design. Hull forms have been developed with somewhat better characteristics than the hull forms of his series. Little excuse exists for any hull form inferior to that of the Taylor Standard Series, the parent Taylor forms.

Since the Standard Series covers a wide range of varying hull proportions, the series may also be used for estimating the residual resistance for hulls that are reasonably similar to that of the series.

Condensed tables of the residual resistance for speed-length ratios from 0.60 to 1.10 and displacement-length ratios from 50 to 250 have been tabulated from the curves of residual resistance of the Taylor Standard Series and are given here in Tables 3 and 4. For purposes of preliminary estimates, these tables are convenient. For values within the ranges given, the residual resistance per ton of displacement may be determined by interpolation. Values also may be obtained for B/H ratios between 2.25 and 3.75 by interpolation between tables. It is to be noted that these tables are taken from curves which are somewhat irregular and that the determination of residual resistance by interpolation is subject to some error. For precise values of residual resistance it is recommended that Taylor's book be consulted.

Table 4.[a] Residual Resistance per Ton (R_r/D). Taylor's Standard Series. $B/H = 3.75$

Where R_r = residual resistance, lb per ton of displacement; D = displacement, tons, 2,240 lb; B = beam, ft; H = draft, ft; V = speed, knots; L = length of water line, ft; C_p = longitudinal prismatic coefficient.

[a] Condensed tables by Prof. K. S. M. Davidson from Rossell and Chapman, "Principles of Naval Architecture," vol. II, Soc. Nav. Arch. and Mar. Engrs.

$$
\begin{array}{lrll}
(j) & 595x = & 595; & \therefore x = 1 \\
 & 5y = & 65 - 55x = 65 - 55 = 10; & \therefore y = 2 \\
 & 19z = & 12 + 19x + 13y = 12 + 19 + 26 = 57; & \therefore z = 3 \\
 & 2w = & 3 - 4x - 3y + 5z = 3 - 4 - 6 + 15 = 8; & \therefore w = 4
\end{array}
$$

Here w is eliminated from (a) and (b), obtaining (e); from (a) and (c), obtaining (f); and from (a) and (d), obtaining (g). Then z is eliminated from (e) and (f), obtaining (h), and from (e) and (g), obtaining (i). Then y is eliminated from (h) and (i), obtaining (j), which contains only the single variable x. Hence $x = 1$. Now substituting this value of x in either (h) or (i), y is found; substituting these values of x and y in either (e), (f), or (g), z is found; and so on. (Solution by determinants, see p. 123.)

Approximate Solution of a Set of Simultaneous Equations of the First Degree When the Number of Equations is Greater Than the Number of Unknowns. (Method of Least Squares.)

Case 1. Single Unknown Quantity. Given n equations in one unknown x; for example, n equally careful, independent measurements of some physical quantity:

$$x = x_1, x = x_2, \ldots x = x_n.$$

As the "best" value of x, take the arithmetic mean, x_0, of the several determinations, namely, $x_0 = (x_1 + x_2 + \ldots + x_n)/n$. The quantities $v_1 = x_0 - x_1$, $v_2 = x_0 - x_2$, $\ldots$ $v_n = x_0 - x_n$ are called the **residuals** of the observed values with respect to x_0, and their absolute values (that is, their numerical values without regard to sign) are denoted by $|v_1|, |v_2|, \ldots |v_n|$. [It can be shown that the sum of the squares of the residuals with respect to x_0 is smaller than the sum of the squares of the residuals with respect to any other value x'_0; hence the name of the method: "least squares."]

The quantities r and r_0, defined exactly by Bessel's formulæ:

$$r = \frac{0.6745}{\sqrt{n-1}}\sqrt{v_1^2 + v_2^2 + \ldots + v_n^2}$$

$$r_0 = \frac{0.6745}{\sqrt{n(n-1)}}\sqrt{v_1^2 + v_2^2 + \ldots + v_n^2}$$

or given approximately by the simpler formulæ of Peters:

$$r = \frac{0.8453}{\sqrt{n(n-1)}}(|v_1| + |v_2| + \ldots + |v_n|)$$

$$r_0 = \frac{0.8453}{n\sqrt{n-1}}(|v_1| + |v_2| + \ldots + |v_n|)$$

are called the **probable error of a single observation** (r), and the **probable error of the mean** (r_0), for the given series of observations. Note that $r_0 = r/\sqrt{n}$. For tables of the coefficients, see p. 63. This quantity r (or r_0) is best regarded as merely a conventional means of recording the relative precision of different sets of observations. If r is small, it may be inferred that most errors of the "accidental" class have been eliminated; but it should be especially noted that the smallness of r gives no information in regard to "constant" or "systematic" errors.

A statement like "x is equal to 2.36 with a probable error of 0.02," is written: $x = 2.36 \pm 0.02$, and is usually understood to mean that the true value of x, as far as can be told, is just as likely to lie inside as outside the

To test the **distribution of residuals**, arrange the residuals in order of magnitude, without regard to sign, and count the number, y, of residuals which are numerically less than some assigned value a; divide y by n, the total number of observations, and divide a by r, the probable error of a single observation. Do this for various values of a, and compare the results with the table on p. 63, which gives the standard distribution of residuals, as found from experience from a large number of different series of observations. In particular, the number of residuals numerically less than r should be about equal to the number numerically greater than r (if n is large). If any large discrepancy appears, the series of observations should be regarded as unsatisfactory.

NOTE. The "mean square error" sometimes met with is equal to the probable error divided by 0.6745.

Case 2. Several Unknown Quantities. Assume that there have been obtained by measurement or observation n different equations of the first degree involving, say, three unknown quantities, x, y, z. There are then n simultaneous equations in three unknowns, and if $n > 3$ there will be, in general, no set of values of x, y, z which will satisfy all these n equations exactly. In such a case, the "best" set of values, x_0, y_0, z_0, may be found by the method of least squares as follows. (The process usually involves a large amount of labor; the use of a computing machine is advisable.)

Given Equations

$$a_1x + b_1y + c_1z = p_1$$
$$a_2x + b_2y + c_2z = p_2$$
$$\cdot \quad \cdot \quad \cdot \quad \cdot$$
$$a_nx + b_ny + c_nz = p_n$$

First, arrange the n given equations in the form indicated, being careful not to modify any of them by multiplication or division. (Any of the coefficients may of course be zero.)

Next, form the three "normal equations" as follows: (1) Multiply each of the given equations by the coefficient of x in that equation, and add; the result will be the first normal equation. (2) Multiply each of the given equations by the coefficient of y in that equation, and add; the result will be the second normal equation. (3) Similarly for the third. {Notation: $[aa] = a_1^2 + a_2^2 + \ . \ . \ . + a_n^2$; $[ab] = a_1b_1 + a_2b_2 + \ . \ . \ . + a_nb_n$; $[ap] = a_1p_1 + a_2p_2 + \ . \ . \ . + a_np_n$; etc.}

Normal Equations

$$[aa]x_0 + [ab]y_0 + [ac]z_0 = [ap]$$
$$[ba]x_0 + [bb]y_0 + [bc]z_0 = [bp]$$
$$[ca]x_0 + [cb]y_0 + [cc]z_0 = [cp]$$

Finally, solve the three normal equations for the three unknowns in the usual way.

The quantities $v_1 = a_1x_0 + b_1y_0 + c_1z_0 - p_1$, etc., are called the **residuals** with respect to x_0, y_0, z_0. [It can be shown that the sum of the squares of the residuals with respect to x_0, y_0, z_0 is smaller than the corresponding quantity with respect to any other set of values, x'_0, y'_0, z'_0; this relation is taken as the criterion for the "best" set of values of x, y, z.]

The probable error of a single observation is

$$r = \frac{0.6745}{\sqrt{n-m}}\sqrt{v_1^2 + v_2^2 + \ . \ . \ . + v_n^2}, \text{ or approximately,}$$

$$r = \frac{0.8453}{\sqrt{n(n-m)}}(|v_1| + |v_2| + \ . \ . \ . + |v_n|),$$

where m = the number of unknown quantities (here $m = 3$).

Example. The following uses Taylor's Standard Series as a basis for estimating the power requirements of an assumed twin-screw ship with dimensions and characteristics as follows: length on water line, $L = 480$ ft; beam, $B = 72$ ft; draft, $H = 25.5$ ft; displacement, $D = 16{,}600$ tons; midship section coefficient, $C_m = 0.963$; longitudinal prismatic coefficient, $C_p = 0.682$; block coefficient, $C_b = 0.651$; and speed, $V = 14.25$ knots. Therefore $B/H = 2.82$; $V/\sqrt{L} = 0.65$; and $D/(L/100)^3 = 150$.

Wetted Surface Calculation:

$$A = C\sqrt{D \times L} \tag{10}$$

from Fig. 1, $C = 15.5$. Therefore,

$$\text{Area of wetted surface} = A = 15.5\sqrt{16{,}600 \times 480} = 43{,}753 \text{ sq ft}$$

Frictional Resistance (R_f):

$$R_f = f \times A \times V^n \tag{26}$$

from Table 2, $f = 0.00905$ (about) and $n = 1.829$. Therefore,

$$R_f = 0.00905 \times 43{,}753 \times 14.25^{1.829} = 51{,}047 \text{ lb}$$

Residual Resistance (R_r):
From Table 3,

$$R_r \text{ per ton displacement } \begin{aligned} &= 1.03 \text{ for } C_p = 0.70 \\ &= 0.83 \text{ for } C_p = 0.60 \end{aligned} \Bigg\} \text{ at } \frac{V}{\sqrt{L}} = 0.65 \text{ and } \frac{B}{H} = 2.25$$

By interpolation, $R_r = 0.994$ for $C_p = 0.682$ of the assumed ship.
From Table 4,

$$R_r \text{ per ton displacement } \begin{aligned} &= 1.39 \text{ for } C_p = 0.70 \\ &= 1.05 \text{ for } C_p = 0.60 \end{aligned} \Bigg\} \text{ at } \frac{V}{\sqrt{L}} = 0.65 \text{ and } \frac{B}{H} = 3.75$$

By interpolation, $R_r = 1.328$ for $C_p = 0.682$ of the assumed ship. By interpolation between $R_r = 0.994$ for $B/H = 2.25$ and $R_r = 1.328$ for $B/H = 3.75$, the R_r of the assumed ship $= 1.121$ lb per ton of displacement at a $B/H = 2.82$.
Therefore the residual resistance of the assumed ship is

$$1.121 \times 16{,}600 = 18{,}609 \text{ lb}$$

Total Bare-hull Resistance (R_t):

$$R_t = R_f + R_r \tag{25}$$
$$R_t = 51{,}047 + 18{,}609 = 69{,}656 \text{ lb}$$

Total Hull Resistance (R_T):
Assuming an appendage resistance of 9 percent of the bare-hull resistance, then

$$R_T = 69{,}656 \times 1.09 = 75{,}925 \text{ lb}$$ (approximately) see p. 1399.

Effective Horsepower:

$$\text{Ehp} = \frac{R_T \times V}{325.5} \tag{28}$$

$$\text{Ehp} = \frac{75{,}925 \times 14.25}{325.5} = 3{,}324 \tag{28}$$

Assuming a propulsive coefficient [Eq. (29)] equal to 0.69, then

$$\text{Shp} = \frac{3{,}324}{0.69} = 4{,}820 \quad \text{(approximately)}$$

propeller is accelerated, and its speed relative to the hull is increased in this region. Obviously, the resistance of the hull will be increased. It is common practice to assume this increase in resistance as a loss in propeller thrust. For such an assumption, the propeller thrust will be greater than the resistance. The ratio of this increase in thrust to the resistance is termed the **thrust deduction coefficient.** Thus,

$$t = \frac{T - R}{T} \tag{35}$$

where T = the propeller thrust in accordance with the foregoing assumption
R = resistance of the ship
t = thrust deduction coefficient

The **wake and thrust deduction** are interrelated and, therefore, may not be considered as totally independent. The interrelationship may be expressed as follows:

$$E_h = \frac{1 - t}{1 - w} \tag{36}$$

where t = thrust deduction fraction
w = wake fraction
E_h = hull efficiency, as defined below

The work done on a ship is equal to the resistance times the speed of the ship through still water, and the work done on the propeller is the thrust times its speed of advance. The ratio of the work done on a ship to the work done by the propeller is termed the hull efficiency.

For purposes of preliminary propeller design, Taylor considered that an assumption of a hull efficiency equal to unity was sufficiently accurate. Such an assumption assumes that any gain from the wake is offset on the loss in propeller thrust. For such an assumption the **wake fraction** will equal the **thrust deduction coefficient.**

Examination of model and trial data indicates that for the average twin-screw ship, Taylor's assumption of a hull efficiency equal to unity is usually satisfactory. However, it appears that the hull efficiency of **single-screw** ships is more likely to range between 1.08 to 1.25. Further, it appears that the hull efficiencies of **triple- and quadruple-screw** ships are likely to range from values less than unity to unity.

Effect of Hull Form on Frictional Resistance. Equation (26) assumes that the hull form affects the frictional resistance only in so far as the form affects the area of the wetted surface and the length of the hull form affects the selection of the frictional constant. (In the case of the Tideman constants, the length of the hull form also affects the exponent n.) Such an assumption is not strictly true. However, for all practical purposes, Eq. (26) will give satisfactory results. For medium-sized vessels, the errors will be negligible. For very large vessels of high speed, the use of Eq. (26) may underestimate the total resistance as much as 10 percent. In the final analysis such vessels require special investigation.

Effect of Hull Form on Residual Resistance. The effect of hull form on the residual resistance is very complex and, to date, no simple analytical methods have been developed for purposes of estimation. In general, the length of the hull form, the prismatic coefficient, the displacement-length ratio, the shape of the curve of sectional areas, and the beam-draft ratio are particularly effective in influencing the residual resistance as follows:

1. The **length of the hull** form is particularly significant. A curve of residual resistance plotted against the speed-length ratio will follow an exponential form with certain irregularities or humps. These humps are caused by the interference of the various wave systems set up in the water at the bow, along the vessel, and at the stern. The first significant hump or rise in the residual resistance occurs at speed-length ratios between about 0.75 to 0.82. The second significant hump occurs at speed-length ratios of about 1.0 to 1.1. The third significant hump occurs at speed-length ratios of about 1.25 to 1.7. Experience has shown that for heavy cargo vessels of full form, speed-length ratios in excess of 0.75 are not economical, and that for fast passenger vessels of the liner type speed-length ratios greater than 1.0 to 1.1 are not practicable. For vessels such as cruisers, destroyers, and yachts where speed is considered paramount, speed-length ratios above 1.1 are often encountered. Such vessels have a large ratio of horsepower to displacement, and large changes in trim will be experienced at high speeds, unless special preventive modifications are made to the hull form. Such modifications are usually in the form of flat sterns, level and straight buttock lines aft, and often hard bilges incorporated with sharp knuckles or chines. All of which generally make for uneconomical hull forms at lower speed-length ratios.

2. The **prismatic coefficient** is an indication of the fineness of the hull form and is particularly significant. Low prismatic coefficients are associated with fine forms and low residual resistances. High prismatic coefficients are associated with full forms, bluff bows and sterns, and high residual resistances. Tables 3 and 4 show the effectiveness of the prismatic coefficient in the Taylor Standard Series.

3. The **curve of sectional areas** has a significant influence on the residual resistance in that, for vessels of normal form, it is closely allied to the prismatic coefficient. For the higher values of speed-length ratios and lower values of the prismatic coefficient, the curve of sectional areas is extremely significant. In general, a form of curve similar to a curve of versed sines gives the least residual resistance. Increasing the prismatic coefficient and reducing the speed-length ratio reduce the significance of the curve of sectional areas accordingly.

4. The effect of varying **displacement-length** and **beam-draft ratios** is significant to a lesser extent in their effect on residual resistance. Tables 3

PROPELLERS

BY

J. M. LABBERTON

REFERENCES: Taylor, "Speed and Power of Ships," Ransdell, Inc. Labberton, "Marine Engineering," McGraw-Hill.

Basic Coefficient and Performance. A propeller is a screw, the length of which is much less than the pitch. As a consequence, if the "thread" or blade were made continuous, it would not cover the complete circumference and the result would be a single-bladed lop-sided propeller. In order to obtain balance, this screw is divided up into two, three, or four blades. Some of the first tests made indicated that efficiency was greatly impaired by too much blade width or too long a screw, owing to the motion of the water past the surface.

In the case of any screw propeller of a given pitch working in a viscous fluid, it can be shown by dimensional analysis that the thrust developed is

$$T = \rho d^2 V_a^2 \left[f\left(\frac{nd}{V_a}\right), \frac{\gamma}{dV_a}, \frac{dg}{V_a^2} \right]$$

where T = propeller thrust, lb
d = propeller diameter, ft
n = propeller rps
V_a = speed of advance, fps
ρ = density of fluid, lb per cu ft
γ = kinetic viscosity of fluid
g = gravity acceleration

It will be noted that the second term in the parenthesis is the Reynolds number inverted and that the third term is Froude's number. For reasons that cannot be covered in the space here available it is known that these last two functions can be neglected in the case of practical propellers not in cavitation and the expression for thrust can be simplified to

$$T = \rho d^2 V_a^2 \times f\left(\frac{nd}{V_a}\right)$$

$f\left(\frac{nd}{V_a}\right)$ is a function of slip and from the above can be derived a dimensionless coefficient $B = \frac{nP^{1/2}}{\rho^{1/2} V_a^{5/2}}$ fixing the performance of any propeller regardless of size but having a given pitch ratio, number of blades, blade proportions, etc., and at a given slip but not in cavitation. However, since water is the only fluid with which we are concerned at present, we can dispense with the variable ρ. Moreover, since it is customary in propeller problems to use knots instead of feet per second and revolutions per minute instead of revolutions per second, V_a = knots and N = rpm can be used. The dimensionless coefficient then becomes a quasi-dimensionless coefficient

$$B_p = \frac{NP^{1/2}}{V_a^{5/2}}$$

and 4 again illustrate their effect on the residual resistance for the Taylor Standard Series. For speed-length ratios in excess of 0.75 to 0.82, the residual resistance rapidly increases in significance.

Resistance of Appendages. Appendages to the hull such as shaft struts, shafts, condenser scoops, plate laps, and bilge keels also induce added resistance. Taylor has indicated that the total resistance of appendages for twin-screw vessels with large bilge keels, two pairs of struts per shaft, may amount to as much as 20 percent of the bare-hull resistance, and that for single-screw vessels without bilge keels the appendage resistance may be as low as 3 to 4 percent of the bare-hull resistance. Careful streamlining of the shaft struts, bosses, etc., to the flow line of the water about the hull is necessary to avoid the high appendage resistance of the first case.

With bilge keels following the lines of flow, the additional resistance of the bilge keel is little different from that of the additional wetted surface.

Resistance in Shallow Water and Restricted Passages. The passage of vessels through restricted channels, such as canals, and through shallow water greatly increases the resistance. Ships of normal form operating in such waters experience a large increase in draft and change of trim, because the lines of water flow are forced out of their normal paths. For vessels passing through canals at moderate speeds where the canal width is about six to 10 times greater than that of the ship, the added resistance will be small; for a ratio of 2.5 or 3, the increase in resistance will be excessive, compelling a speed so low as to prohibit operation for vessels of normal form. Depths of water greater than six to ten times the draft are required for vessels of the slow-speed type; depths greater than the length of the vessel are required for high-speed types in order that the resistance may be free from the effects of shallow water. Vessels designed for operation in shallow or restricted water require special consideration.

Air Resistance. The above-water portion of a ship's hull and superstructure moving through the air also induces resistance to the forward motion of the ship. In the case of water resistance the ship advances directly into the water, but it does not always advance directly into the wind except in the case of a head wind. More often the wind would be abeam or astern, in which case it may assist the forward motion of the ship. In general, the air or wind resistance is only a small fraction of the water resistance and may often be neglected.

Taylor indicated that reasonably good estimates of air resistance may be calculated by the following formula:

$$R_a = 0.004 \frac{B^2 \times V_a^2}{2} \tag{27}$$

where R_a = air resistance, lb

B = beam of ship, ft

V_a = speed of wind, knots

This formula assumes that the projected area presented to the wind is equal to $B^2/2$. (The ship is assumed to be half the beam in height above the water.)

Effective Horsepower. The effective horsepower may be defined as the "towrope" horsepower or the power transmitted through a towrope, assuming the vessel to be towed at a given speed, and may be calculated by the following relationship:

where the subscript p indicates that the coefficient is concerned with power input to the propeller rather than the useful power output.

Therefore, if any model propeller is tested at a given slip and rpm, and if power input in horsepower and speed of advance in knots are measured, the coefficient B_p can be determined which will hold good for any size of propeller, of geometrically similar proportions. If

$$\delta = \frac{Nd}{V_a} \quad \text{and} \quad a = \frac{p}{d} \text{ the pitch ratio,}$$

then it can be shown that $1 - S = \frac{101.33}{a\delta}$ where S is slip ratio, that percentage of a propeller revolution turned which does not advance the propeller in proportion to pitch.

From the foregoing it follows that, in similar manner, the power output, U, of the propeller could be used as well as the power input, P, and a similar coefficient

$$B_u = \frac{NU^{1/2}}{V_a^{5/2}}$$

would result, the only difference being the factor of efficiency. If e_p = propeller efficiency, $e_pP = U$,

or

$$B_p\sqrt{e_p} = \frac{NU^{1/2}}{V_a^{5/2}} = B_u$$

Naturally, a plot of values of B_u is much more valuable than a plot of B_p because it is generally required to choose a propeller for a given job rather than to determine what a given propeller, already chosen, will do.

Figures 1 and 2 show plots of three- and four-bladed propeller performance as made by Rear Admiral D. W. Taylor, USN, from tests made at the Washington Navy Yard. Figure 3 shows corrections to be made when the propeller has a mean width ratio (M.W.R.) or a blade thickness fraction (B.T.F.) other than M.W.R. = 0.25 or B.T.F. = 0.05, the conditions covering Figs. 1 and 2.

It will be noticed that as the values of the B_u increase the maximum efficiency obtainable decreases and the correct pitch ratio to obtain this maximum efficiency also decreases. It will be noted that there is one best value of $\delta = \frac{Nd}{V_a}$ and one pitch ratio that should be used to obtain the highest possible efficiency for a given B_u.

A curve has been drawn on Figs. 1 and 2 through these maximum efficiency points. Mention has been made of mean width ratio and blade thickness fraction. Figure 4 shows a conventional elliptical blade with a 20 percent diameter, hub. The term conventional elliptical blade is used because that is the general shape of the blade as recommended by Dyson. The characteristics of such blades are set forth in Fig. 6 where, with a propeller radius of unity, the chords of the arcs between the middle line of the projected area and either leading or following edge of the projection at each of the

$$\text{ehp} = \frac{R_T \times V}{326} \tag{28}$$

where ehp = effective horsepower
R_T = total resistance, lb, of the ship including bare hull, appendage, and air resistance
V = speed, knots

Propulsive Coefficient. The ratio of ehp to shp is termed the propulsive coefficient, *i.e.*,

$$\frac{ehp}{shp} = \text{propulsive coefficient} \tag{29}$$

The term indicated horsepower is applied in the case of reciprocating machinery. In the case of modern steam-turbine-driven vessels or diesel electric vessels, the shaft horsepower (shp) is used. Similarly, for diesel- or gasoline-powered vessels, the brake horsepower (bhp) is used in lieu of ihp. It is to be noted that the ihp includes the necessary power to overcome the losses of the propeller, shaft (stuffing boxes and bearings), and the mechanical efficiency of the engine. The shp is the horsepower in the shaft and does not include the power losses in the reduction gears or turbine machinery. In the case of diesel or gasoline engines the power delivered by the engine at the coupling is termed the brake horsepower (bhp). It is apparent that the propulsive coefficient must be defined specifically in regard to ihp, shp, or bhp.

Propulsive coefficients ranging from 0.40 to 0.70 may be expected when referred to ihp and, when the coefficient is referred to shp, values ranging from 0.50 to 0.80 may be expected. In cases where the mechanical efficiencies are high, values in the upper half of the ranges given may be expected. However, conservative estimates are in order.

Power by Admiralty Formula. The power requirements to propel a ship are often estimated directly by assuming that the total resistance, R_T, is proportional to $D^{2/3} \times V^3$ and that the propulsive coefficient is constant. With such an assumption the following relationship can be expressed:

$$\text{hp} = \frac{D^{2/3} \times V^3}{K} \quad \text{(Admiralty formula)} \tag{30}$$

where hp = engine indicated horsepower, brake, or shaft horsepower
D = displacement, tons
V = speed, knots
K = the Admiralty coefficient.

The Admiralty coefficient includes all factors due to the influence of form, dimensions, propeller, and shaft efficiencies. In cases where the ihp is used in the relationship, it will also include the mechanical efficiency of the engine. It is extremely pertinent to note that for speeds less than about $0.75\sqrt{L}$, the Admiralty coefficient is relatively constant for a particular hull. For speeds in excess of about $0.75\sqrt{L}$, the coefficient may vary irregularly with the speed. Therefore, it is to be noted that considerable experience is required to select a proper coefficient. The following briefly furnishes guidance in selecting a coefficient.

values 0.2, 0.3, 0.4, 0.5, etc., of the radius are given for each value of projected-area ratio of a three-bladed propeller, from $PA/DA = 0.15$ to $PA/DA = 0.7$.

$$\frac{PA}{DA} = \frac{\text{projected area including all blades}}{\text{disk area}}$$

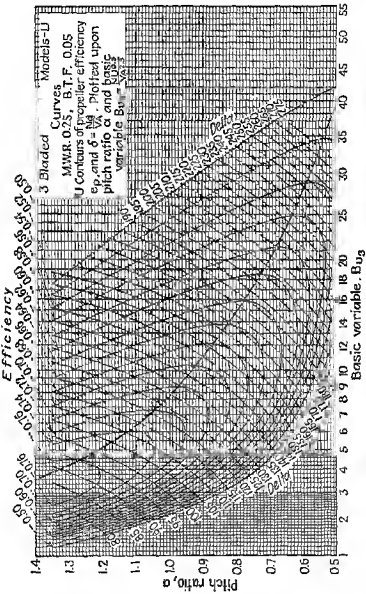

FIG. 1.—Performance of Taylor's series of three-bladed propellers. (*From Admiral D. W. Taylor, U.S.N., The Speed and Power of Ships, Ransdell, Inc.*)

For a four-bladed propeller, the conventional form corresponding to the total projected-area ratio will be for three-fourths of that ratio; for a two-bladed propeller it would be $1\frac{1}{2}$ times that ratio.

In laying down the projected-area form for any desired projected-area ratio it should be borne in mind that all projected areas are outside the $0.2R$

Admiralty Coefficient Values. For ships of large size and with fine to medium characteristics of form (in particular the prismatic coefficient) at speeds such that $V/\sqrt{L} \leqq 0.8$ to 0.9, values of $K = 250$ to 350 are found. For similar ships at higher speed when $V/\sqrt{L} \geqq 1.0$, the values of K range from 250 to 275.

With medium to full hull forms at speeds where $V/\sqrt{L} < 1.0$, K values of 220 to 250 are common.

With medium to small ships, other things being equal, the values range somewhat smaller than for large ships. With medium to small ships of average characteristics and at speeds where $V/\sqrt{L}$ may considerably exceed 1.0, K values of 150 to 200 are common.

For small craft of fine lines driven at excessively high speed and of such underwater form as to rise partly out of the water, the resistance is decreased with corresponding reduction in power and an increase in the value of K. In such cases, values of 200 to 250 and more are met.

For similar ships driven at corresponding speeds, the value K will be the same.

It will be noted from the foregoing that no exact rules can be given for selecting the value of K. Table 5 of ship data is useful and may be used in estimating the proper value for K. Care should be exercised in using ship data for selecting values of K, so that the similarity of the ships is as close as the available data permit.

By the application of **Froude's law of comparison,** extended to cover approximately all components of ship resistance, much more reliable results may be determined. The law may be restated that for similar ships at corresponding speeds the powers will be in the ratio of the products of the displacements by the speeds, or the power ratio will equal the product of the displacement ratio by the speed ratio.

Thus, given a ship having a length of 400 ft, a displacement of 7,500 tons, a speed of 16 knots, and requiring 0,300 ihp, by substitution in Eq. (30) the value of K is readily found to be 250. Then, assuming a similar ship 480 ft in length; length ratio $= 480/400 = 1.2$; corresponding speed ratio $= \sqrt{1.2} = 1.095$; corresponding speed $= 16 \times 1.095 = 17.53$; displacement ratio $= (1.2)^3 = 1.728$; displacement $= 7,500 \times 1.728 = 12,960$. Then using value of $K = 250$, displacement $= 12,960$, and speed $= 17.53$ and substituting in Eq. (30), the ihp required at the corresponding speed will be 11,900. For moderate differences in block coefficient, C_b, and in length to beam ratio, L/B, K may be taken to vary inversely as $(C_b)^{2/3}$ and $(\text{beam})^{1/3}$.

Power by Stevens Formula. A modification of the Admiralty formula known as the Stevens formula is sometimes used with fairly good results:

$$\text{hp} = \frac{D \times V^3}{C \times \sqrt{L}} \qquad \text{(Stevens formula)} \quad (31)$$

where hp = engine ihp or bhp
D = displacement, tons (2,240 lb per ton)
L = length, ft, of load water line
C = a coefficient to be selected

Values of C may be estimated from nearly similar ships. Table 5 may again be used for this purpose. Values of C are given in Fig. 5. The two curves that are plotted upon displacement show the limits through which

circle, and any variation from this in the actual blade due to variation of the hub diameter may be neglected. The lengths of the chords of the half arcs for any diameter propeller will equal the length of the chord as given in the table for each fraction of the radius and the particular projected-area ratio desired, multiplied by the radius of the propeller.

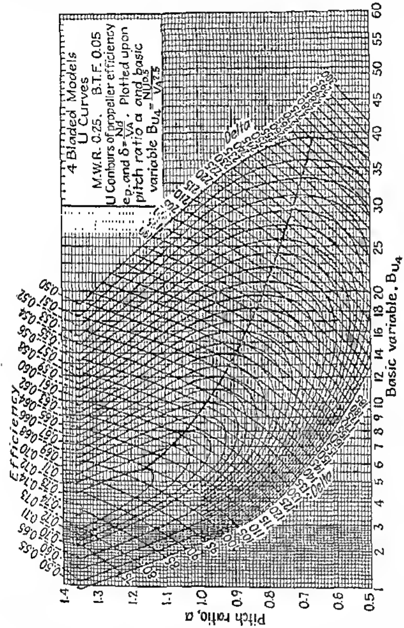

FIG. 2.—Performance of Taylor's series of four-bladed propellers. (*From Admiral D. W. Taylor, U.S.N., The Speed and Power of Ships, Ransdell, Inc.*)

Thus, suppose the diameter of the propeller to be 10 ft and the desired projected-area ratio to be 0.6. The length of the chord at the half arc at $0.7R$ will be $0.499 \times 5 = 2.495$ ft.

The greatest circular width of the projected-area form for conventional elliptical blades is at the $0.7R$ radius.

The term projected-area ratio or PA/DA is falling into disuse, probably because it does not take pitch into account, and mean width ratio is taking its place.

Figure 4 shows the developed outline of the conventional elliptical blade above the 20 percent hub. If the area of this developed blade is divided by the distance from the hub to the tip, the result will be a mean width, a very important dimension. Mean width divided by the diameter of the propeller results in a dimensionless ratio called the mean width ratio, which is a measure of the proportionate size of the blade, its surface area, and, con-

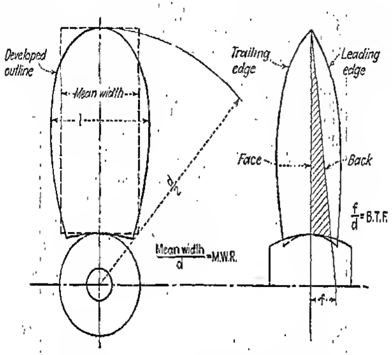

FIG. 4. FIG. 5.
Conventional elliptical blade and nomenclature.

sequently, unit surface pressure which has to do with cavitation as will be discussed later.

Therefore, referring to Fig. 4 and its notation, $\dfrac{\text{mean width}}{d} = \text{M.W.R.}$

With reference to the conventional forms

$$\frac{PA}{DA} = (0.543 - 0.1106a)n(\text{M.W.R.})$$

where a = pitch ratio, $\dfrac{p}{d}$

n = number of blades

The maximum developed width of the blade can be determined by the expression

$$l = 1.188(\text{M.W.R.})d$$

C may vary. These curves were derived from ships with a ratio of beam to draft (B/H) of about 2 and $V/\sqrt{L}$ of 0.5 to 0.6. Ships with shallower draft and higher speed-length ratios will fall near the lower curve; deeper draft ships of moderate speed-length ratios and good form will fall near the upper curve. Ships of higher speed-length ratios and with propellers making a high number of revolutions, values of C, will fall below the lower curve. It is to be noted that values of C taken from the curves of Fig. 5 are for use with the formula when hp = ihp and assuming that ihp = 2 × ehp.

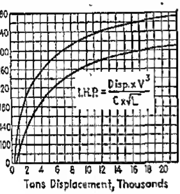

FIG. 5

Other Formulas for Estimating Power. In addition to the Admiralty formula and the Stevens formula, other and lesser known relationships are sometimes used for estimating power requirements:

$$V = \frac{C\sqrt[3]{L \times \text{hp}}}{B} \tag{32}$$

where V = speed, knots
L = length, ft, of water line
hp = horsepower
C = coefficient to be selected
B = beam, ft.

Also,

$$V = \sqrt[3]{\frac{\text{hp} \times 1{,}000}{D}} \times \sqrt{L} \times C \tag{33}$$

where V = speed, mph (5,280 ft per hr)
D = displacement, lb
L = length of water line, ft
hp = horsepower
C = a coefficient to be selected

In Eqs. (32) and (33) selection of a proper coefficient, as in the Admiralty formula, requires experience and judgment, and similarly to the Admiralty coefficient the value of C includes many factors. It is pertinent to note that Eq. (33) is in common use in the field of motorboat designing and good results may be obtained for such vessels.

Power Requirements. In estimating the power requirements, it is pertinent to note that the foregoing methods of calculating power by the use of model tests, similar ships, or Taylor's Standard Series give trial-trip speeds. In the case of the Admiralty or Stevens formula, the coefficients are often calculated on trial-trip conditions. Trial trips are usually made under ideal conditions of clean bottoms and fair weather. Service conditions are far different. Semifoul bottoms and bad weather are to be expected. The final selection of the power requirements should provide for maintenance of service speed, and an additional allowance in power should be provided. Experience has shown that increases ranging from 20 to 35 percent are in order depending upon the vessel and the conditions of the service in which the vessel will operate. Slow-speed vessels of full form are less apt to be retarded by heavy weather than vessels of fine form. Foul bottoms will usually slow down fine-lined fast vessels more than slow full-form cargo vessels.

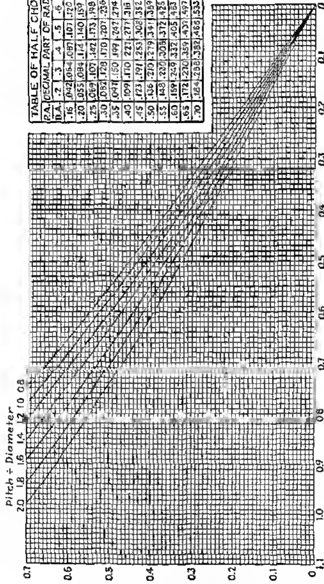

FIG. 6.—Dyson's standard forms of propellers. (*Courtesy*

WAKE AND WAKE FRACTION

The speed of a ship, the friction of the water, the roughness of the wetted surface, the hull form, and the appendages create a tendency to drag a boundary layer of water along with its movement. The water closely adjacent to the wetted surface moves with the speed of the ship, and its speed rapidly decreases toward the outward extremities of the layer. The thickness of this moving layer of water is at a minimum at the bow and increases in thickness progressively toward the stern. There, the forward motion of the water on the surface is often augmented by the stern wave. This whole effect of moving water is termed the **wake**, and its speed is maximum directly astern of the sternpost and retrogressively decreases away from this vicinity of the ship. The effect of the wake is that of the propeller doing its work advancing through a current of water at a speed different from that of the ship moving through the surrounding still water. The speed of the propeller advancing through the wake is termed the **speed of advance** and is defined in accordance with the following relationship:*

$$V_a = (1 - w)V \tag{34}$$

where V_a = speed of advance, knots
V = speed of ship through still water, knots
w = wake fraction

It is of interest to note that the propeller derives from the wake in which it is working an increased thrust resulting in a return to the vessel of a portion of the energy spent in overcoming the resistance. Since the propellers of single-screw ships are in the region of maximum wake, it follows that such ships will benefit more from this source than multiscrew ships.

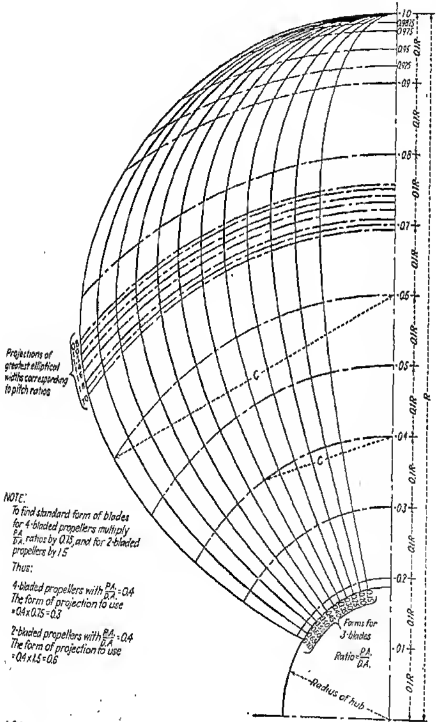
Obviously, the wake fraction is of major importance to the propeller designer. Selection of a proper wake fraction can best be made from the results of tests with models fitted with appendages and propellers. In the absence of such tests, the following derived from data published in the Taylor and *Trans. Soc. Nav. Arch. and Mar. Engrs.*, references, given at the beginning of this article, will furnish guidance for approximating the value of the wake fraction:

1. For the average single-screw ship, the wake fraction in the vicinity of the screw ranges approximately in a straight-line relationship from 0.15 for ship speeds of 20 knots to 0.35 for ship speeds of 14 knots. For ships of full form with high block coefficients, higher values may be expected.

2. For the average twin-screw ship, the wake fraction in the vicinity of the screws ranges approximately in a straight-line relationship from 0.05 for ship speeds of 30 knots to 0.20 for ship speeds of 14 knots. For ships of finer than average form and with low block coefficients, lower values of the wake fraction may be expected. For ships of light displacement and high speeds, slightly negative values are often encountered. For ships of more than average full form, the wake fraction may be expected to be greater than the values given.

3. For triple-screw ships where the center screw is aft and relatively clear of the wash of the outboard wing screws, the wake fraction for the center screw may be expected to be slightly less than that for single-screw

* Froude expressed the relationship as $V/V_a = (1 + x)$, where x = wake percentage. Thus $w = \dfrac{x}{1 + x}$. The wake fraction is not to be confused with the wake percentage.



of Simmons-Boardman Publishing Corporation.)

ships. The wake fraction for the wing screws will have values about the same as given for twin-screw ships.

4. For quadruple-screw ships, the establishment of average values of the wake fraction in the vicinity of the screws is especially difficult. In most quadruple-screw ships it is quite difficult and often impracticable to locate the outboard or inboard screws so that the inboard screws may be entirely free of the wash of the outboard screws. Therefore, it may be expected that the wake fraction of the inboard screws will be somewhat less than the values given for twin-screw ships. Since the outboard screws are usually farther away from the maximum wake, it may be expected that the wake values of the same will generally be slightly less than that of the inboard screws.

It is to be noted that there is a general relationship between the block coefficient and the wake fraction. High wake fractions are generally associated with high block coefficients, and low wake fractions are generally associated with low block coefficients.

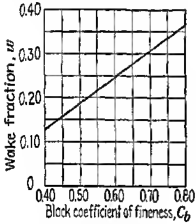


FIG. 6.—Wake fraction for single-screw ships.

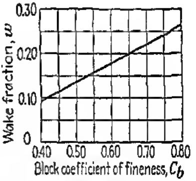

FIG. 7.—Wake fraction for twin-screw ships.

Taylor, by approximate determination from numerous trial results of full-size ships, derived wake fraction values for twin-screw ships ranging from −0.038 for ships with block coefficients of 0.50 to values of 0.200 for ships with block coefficients of 0.80. The wake fraction values of single-screw ships ranged from 0.230 for ships with block coefficients of 0.50 to values of 0.477 for ships with block coefficients of 0.90. Since low block coefficients are generally associated with fine form, it is reasonable to presume that the fine forms were driven at higher than average speeds (see Figs. 6 and 7).

The subject of the wake fraction has been investigated by many authorities, and the trends of values of the fraction are generally consistent. However, the establishment of wake fraction values by means of a relationship correlating influencing factors has not been entirely satisfactory or consistent in the determination of numerical values. In the absence of specific test data it is suggested that Figs. 6 and 7 be used.

Thrust Deduction Coefficient and Hull Efficiency. The propeller, doing its work in the stern wake, disturbs the streamlines of the water flow as they close in about the stern. The water approaching and leaving the

For values of a between 0.6 and 2.0 the following expressions hold:

$$\text{Total developed blade area} = 0.4nd^2(\text{M.W.R.})$$
$$\text{Projected area} = PA = (0.4267 - 0.0916a)nd^2(\text{M.W.R.})$$
$$\frac{PA}{\text{Developed area}} = 1.067 - 0.229a$$
$$\frac{\text{Developed area}}{\text{Disk area}} = 0.509n(\text{M.W.R.})$$

There is a limit to mean width ratio vitally affecting efficiency. The reason for increasing the blade width is to decrease the unit pressure, but naturally this presents more surface for drag friction. This loss of efficiency

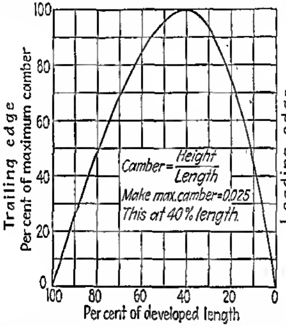

FIG. 7.—Streamline blade sections. Center-line cambers.

progresses fairly proportionately until a value of approximately 0.50 for mean width ratio is reached, and then there is a sudden great increase in the loss and the efficiency falls off very rapidly.

In Fig. 5 the face is shown as a straight line. When this straight line revolves at a constant angular velocity and moves forward at a constant linear velocity, a helicoidal surface is generated, which is the face of the propeller blade. Generally the straight line is perpendicular to the axis of rotation; sometimes, in order to clear some part of the hull, the straight line, or generatrix, is inclined. In either event, the propeller action is the same.

The propeller blade acts as a cantilever beam with a distributed load, the total load being the total pressure upon the blade. The stress then depends, for a given load, on the section modulus at the root or point where the blade joins the hub. Since this is true, the thicker the blade at the root, the less the stress or the stronger the blade or the stronger the propeller. A measure

DETERMINANTS

Determinants are used chiefly in formulating theoretical results; they are seldom of use in numerical computation.

Evaluation of Determinants:

Of the second order:

$$\begin{vmatrix} a_1 b_1 \\ a_2 b_2 \end{vmatrix} = a_1 b_2 - a_2 b_1$$

Of the third order:

$$\begin{vmatrix} a_1 b_1 c_1 \\ a_2 b_2 c_2 \\ a_3 b_3 c_3 \end{vmatrix} = a_1 \begin{vmatrix} b_2 c_2 \\ b_3 c_3 \end{vmatrix} - a_2 \begin{vmatrix} b_1 c_1 \\ b_3 c_3 \end{vmatrix} + a_3 \begin{vmatrix} b_1 c_1 \\ b_2 c_2 \end{vmatrix}$$

$$= a_1(b_2c_3 - b_3c_2) - a_2(b_1c_3 - b_3c_1) + a_3(b_1c_2 - b_2c_1)$$

Of the fourth order:

$$\begin{vmatrix} a_1 b_1 c_1 d_1 \\ a_2 b_2 c_2 d_2 \\ a_3 b_3 c_3 d_3 \\ a_4 b_4 c_4 d_4 \end{vmatrix} = a_1 \begin{vmatrix} b_2 c_2 d_2 \\ b_3 c_3 d_3 \\ b_4 c_4 d_4 \end{vmatrix} - a_2 \begin{vmatrix} b_1 c_1 d_1 \\ b_3 c_3 d_3 \\ b_4 c_4 d_4 \end{vmatrix} + a_3 \begin{vmatrix} b_1 c_1 d_1 \\ b_2 c_2 d_2 \\ b_4 c_4 d_4 \end{vmatrix} - a_4 \begin{vmatrix} b_1 c_1 d_1 \\ b_2 c_2 d_2 \\ b_3 c_3 d_3 \end{vmatrix}$$

etc. In general, to evaluate a determinant of the nth order, take the elements of the first column with signs alternately plus and minus, and form the sum of the products obtained by multiplying each of these elements by its corresponding **minor**. The minor corresponding to any element a_1 is the determinant (of next lower order) obtained by striking out from the given determinant the row and column containing a_1.

Properties of Determinants.

1. The columns may be changed to rows and the rows to columns:

$$\begin{vmatrix} a_1 b_1 c_1 \\ a_2 b_2 c_2 \\ a_3 b_3 c_3 \end{vmatrix} = \begin{vmatrix} a_1 a_2 a_3 \\ b_1 b_2 b_3 \\ c_1 c_2 c_3 \end{vmatrix}$$

2. Interchanging two adjacent columns changes the sign of the result.
3. If two columns are equal, the determinant is zero.
4. If the elements of one column are m times the elements of another column, the determinant is zero.
5. To multiply a determinant by any number m, multiply all the elements of any one column by m.
6. $$\begin{vmatrix} a_1 + p_1 + q_1, & b_1 & c_1 \\ a_2 + p_2 + q_2, & b_2 & c_2 \\ a_3 + p_3 + q_3, & b_3 & c_3 \end{vmatrix} = \begin{vmatrix} a_1 b_1 c_1 \\ a_2 b_2 c_2 \\ a_3 b_3 c_3 \end{vmatrix} + \begin{vmatrix} p_1 b_1 c_1 \\ p_2 b_2 c_2 \\ p_3 b_3 c_3 \end{vmatrix} + \begin{vmatrix} q_1 b_1 c_1 \\ q_2 b_2 c_2 \\ q_3 b_3 c_3 \end{vmatrix}$$
7. $$\begin{vmatrix} a_1 b_1 c_1 \\ a_2 b_2 c_2 \\ a_3 b_3 c_3 \end{vmatrix} = \begin{vmatrix} a_1 + mb_1, & b_1 & c_1 \\ a_2 + mb_2, & b_2 & c_2 \\ a_3 + mb_3, & b_3 & c_3 \end{vmatrix}$$

Solution of Simultaneous Equations by Determinants.

If
$$\begin{aligned} a_1x + b_1y + c_1z &= p_1 \\ a_2x + b_2y + c_2z &= p_2 \\ a_3x + b_3y + c_3z &= p_3 \end{aligned} \quad \text{where } D = \begin{vmatrix} a_1 b_1 c_1 \\ a_2 b_2 c_2 \\ a_3 b_3 c_3 \end{vmatrix} \neq 0,$$

then
$$\begin{aligned} x &= D_1/D, \\ y &= D_2/D, \text{ where } D_1 = \begin{vmatrix} p_1 b_1 c_1 \\ p_2 b_2 c_2 \\ p_3 b_3 c_3 \end{vmatrix}, \; D_2 = \begin{vmatrix} a_1 p_1 c_1 \\ a_2 p_2 c_2 \\ a_3 p_3 c_3 \end{vmatrix}, \; D_3 = \begin{vmatrix} a_1 b_1 p_1 \\ a_2 b_2 p_2 \\ a_3 b_3 p_3 \end{vmatrix} \\ z &= D_3/D, \end{aligned}$$

Similarly for a larger (or smaller) number of equations.

THE ALGEBRA OF IMAGINARY OR COMPLEX QUANTITIES

In the algebra of imaginary or complex quantities, the objects on which the operations of the algebra are performed are not numbers in any ordinary sense of the word, but are best thought of as **points in a plane** (or as **vectors** drawn from a fixed origin to these points). The "**complex plane**" is determined by three fundamental points, O, U, i, arranged as in Fig. 2 and called the **zero point**, the **unit point**, and the **imaginary unit point**, respectively. All points on the line through O and U are called **real points**—positive if on the right of O, negative if on the left. All the remaining points in the plane are called **imaginary points**—those on the line through O and i being called the **pure imaginary points**.

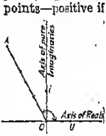

FIG. 2.

The position of any point A in the plane may be determined by the *distance* from the origin O, measured in terms of OU as the unit length, and the *angle* φ which OA makes with the positive direction of the axis of reals. The distance r is sometimes called the modulus or absolute value of the point; the angle φ is sometimes called the amplitude or argument of the point. The notation $A = (3, \angle 120°)$ means the point whose *distance*, r, is 3 times OU, and whose *angle*, φ, is 120°. The development of the algebra depends wholly on the definitions of three fundamental operations denoted by $A + B$, $A \times B$, and e^A, as follows.

Addition and Subtraction. The **sum**, $A + B$, of two points A and B is defined as the point reached by starting from A and performing a journey *equal in length and direction to the journey from O to B. That is, the vector* from O to $A + B$ is the vector sum of the vectors OA and OB. In case A and B are not in line with O, the point $A + B$ is the fourth vertex of a parallelogram of which OA and OB are the sides (Fig. 3). Conversely, if any two points A and B are given, there is a definite point X such that $A = B + X$; this point X is called the **remainder**, A minus B, and is denoted by $A - B$. The point $O - B$ is denoted for brevity by $-B$. With these definitions of $A + B$ and $A - B$, all the ordinary laws of addition and subtraction that hold in the algebra of real numbers hold also in the algebra of complex quantities. In particular, the zero point O has all the formal properties of the number zero, and is denoted by 0.

FIG. 3.

[Note: If A and B are "real" points, $A + B$ and $A - B$ will also be real.]

Repeated Addition. Multiples and Submultiples. The point $A + A + A + \ldots + A$ to n terms is called the **nth multiple of A** and is denoted by nA. The points U, $2U$, $3U$, . . . are denoted, for brevity, by 1, 2, 3, ... Conversely, if any point A, and any positive integer n are given, there is a definite point X such that $nX = A$; this point X is called the **nth submultiple of A**, and is denoted by A/n. The points $U/2$, $U/3$, . . . are denoted, for brevity, by ½, ⅓, ...

Multiplication and Division. The **product**, $A \times B$, or $A{\cdot}B$, or AB, of two points A and B is defined as the point whose angle is the sum of the angles of the given points, and whose distance is the product of the distances. (See Fig. 4.) Thus, if $A = (5, \angle 120°)$ and $B = (2, \angle 270°)$, then $AB = (10, \angle 30°)$. Conversely, if any two points A and B are given, provided B is not zero, there is a definite point X such that

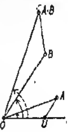

FIG. 4.

of this proportionate thickness is a measure of proportionate strength. This thickness is usually designated as the **blade thickness fraction** and is the ratio between the length of the axial intercept between the front and back lines (extended to the axis) of a central radial section of the propeller blade and the diameter of the blade (see Fig. 5). B.T.F. $= f/d$.

In times past it was usual to make the circumferential section through the blade ogival in shape or as a portion cut from a disk. Recently, owing to the marked advance in the science of fluid mechanics, it has been found that blades of "airfoil" section offer much less resistance to the flow of water past, and consequently a somewhat higher efficiency propeller is the result. This increase in the efficiency due to the adoption of airfoil section is not

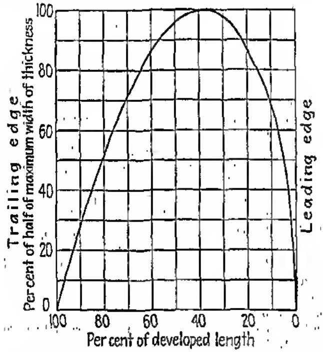

FIG. 8.—Streamline blade sections. Streamline contours about center line.

marked, being a matter of several percent. Also, it has been found that airfoil sections tend to increase cavitation, all other things being equal, because the airfoil section is thicker.

One system of streamlining is covered in Figs. 7 and 8. This is based on the conception of the blade section resembling the plan view of a fish. Assume the backbone or center line of the fish to be curved or cambered so that one side of the fish is fairly flat. This flat side would be the driving face. Having fixed the length of the section according to Fig. 6, the center-line camber is determined according to Fig. 7. The blade thickness, for strength reasons, having been fixed as discussed later, the streamline contours about the curved or cambered center line are determined according to Fig. 8.

Since propellers have been discussed up to this point on a proportionate basis, the law of comparison between a large and a small, or model, propeller will now be given.

(wake and thrust deduction must be taken into account as in the case of propellers working forward) and a given rpm. The curve shown in Fig. 12 is from an actual propeller. Note that

$$\frac{T/V^2d^2}{Q/V^2d^3} = \frac{Td}{Q} = 5.5$$

This latter relationship holds approximately for all propellers regardless of number of blades, blade shape, or pitch.

If it is more convenient, the curve can be obtained by running at one value of water speed and varying the rpm of the model propeller. Note

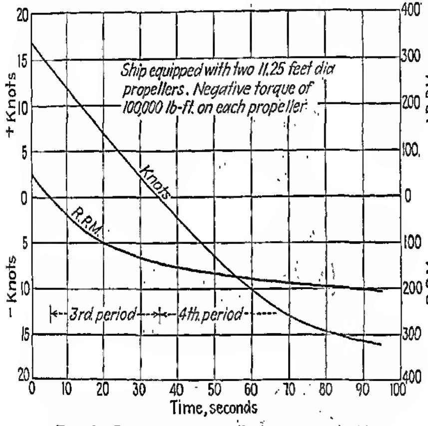

FIG. 13.—Performance of propeller in reverse or backing.

that when Nd/V is zero, the rpm is zero but thrust and torque remain. The different phases in the reversing or backing operation as listed above are indicated on the curve, Fig. 12. Phase 1 is, of course, normal forward operation of the propeller and would not appear on the reverse-operation curve. To obviate any confusion that may be due to negative torque existing during phase 1, note that if there were zero torque, the propeller would pass through this phase but not quite so quickly. The practical effect of this is that a few seconds can elapse between the time the ahead throttle is closed and the reverse is opened with no appreciable effect on the "ahead-reach" or distance it takes for the ship to come dead in the water.

Figure 13 shows the performance of an actual ship in reverse.

Kort Nozzles. The Kort nozzle is a nozzle or ring of airfoil section in which the propeller rotates. Naturally, since space is occupied by the nozzle

Law of Comparison

Diameter, ft	D	d
Rpm	N	n
Speed on advance, knots	V	v
Thrust, lb	T	t
Torque, lb-ft	Q	q
Pressure on propeller, psi	P_1	p_1
Power absorbed	P	p

λ = ratio of linear dimensions.

$$D = \lambda d \qquad Q = \lambda^4 q$$
$$T = \lambda^3 t \qquad V = v\sqrt{\lambda}$$
$$N = \frac{n}{\sqrt{\lambda}} \qquad P = \lambda p_1$$
$$P = \lambda^{3.5} p$$

These equations hold until cavitation starts.

It should be mentioned here that, in running tests to determine the performance of a small model in order that this performance may be converted to that of a propeller of large proportions, elaborate equipment is necessary if there is any likelihood that the large propeller might operate near the cavitation point. This equipment is necessary in order to obtain less than atmospheric pressure on the surface of the water in which the test is run.

Such tests are usually run in a water tunnel with a vacuum pump attached and controls so arranged that the desired pressure will be maintained on the water surface throughout the test. It is beyond the scope of this book to describe the detailed operation of such a water tunnel.

As will be brought out later, the pressure on the propeller has a great effect on the point at which cavitation or boiling will occur. As an example of this phase of model performance, consider the case of a ship that is to be equipped with a 15 ft diam propeller with 4-ft tip submergence. This is equivalent to 11.5 ft water at the hub plus atmospheric pressure of 15 psi 11.5 ft $\times$ 0.4335 = 5 psi. $P = 5 + 15 = 20$ psi abs pressure on the hub.

Suppose a 6-in. model is to be run in order to predict therefrom the performance of the 15-ft propeller.

$$\lambda = \frac{15}{0.5} = 30$$

$$p_1 = \frac{P_1}{\lambda} = \frac{20}{30} = 0.67 \text{ psi}$$

or 1.36 in. Hg abs. With a 30-in. barometer this would correspond to a negative manometer reading of 28.64 in. vacuum.

Tests that are run with full atmospheric pressure on the surface of the water are called "open-water" tests. All readings below the point at which cavitation would occur if the proper pressure were on the propeller are quite accurate. In other words, below cavitation, pressure does not appreciably affect torque and thrust readings.

This extra-large proportionate pressure which exists in the case of small propellers operating in open water is one reason why motorboat propellers can operate at such high values of rpm without cavitation difficulties. It is also the reason why self-propelled tests of ship's models in open water are not always a true measure of performance, especially at the highest powers.

or ring surrounding the propeller, a propeller of smaller diameter must be installed than would otherwise be possible. The advantage of this arrangement is that the thrust is increased at speeds below approximately 8 knots. Therefore, the device is of some advantage when applied to tugs, trawlers, or

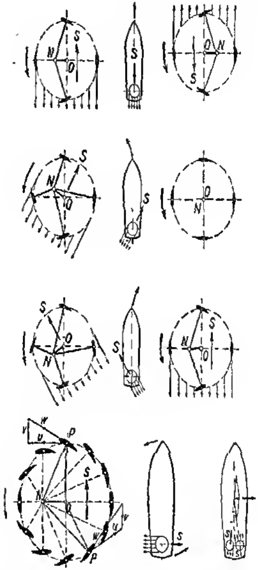

FIG. 14.—Voith-Schneider propeller action.

river towboats. Above approximately 8 knots the arrangement is less efficient than is the conventional propeller.

Voith-Schneider Propeller. The Voith-Schneider propeller consists of an assembly containing long blades of airfoil section projecting vertically downward. This assembly is so arranged that the blades project downward from the after part of the ship's bottom. There may be one or more such

All those concerned with the testing of ship's models under self-propelled conditions dream of the time when they will have a variable-pressure basin in which all factors are adjusted.

In order to choose a propeller for a given job it is necessary to have all the data for the determination of B_u. Required are N, the rpm of the propeller: U, the useful horsepower; and V_a the speed of advance of the propeller.

The useful horsepower, U, is that part of the initial shaft horsepower (shp) which is available for propulsion after the propeller losses are taken into account. Having the useful horsepower the hull effect must be considered in order to obtain the actual work on the ship, which is, of course, the effective horsepower (ehp) of the ship at that speed (see p. 1399).

The hull efficiency may be greater than 100 percent, and consequently the useful horsepower be less than the ehp. A strong wake helps or increases the hull efficiency, whereas a strong or heavy thrust deduction detracts from it.

Wake effect is specified as "wake fraction" and is the speed of the wake divided by the speed of the ship with reference to undisturbed water. Since the propeller operates in water, the speed of advance of the propeller through the water in which it finds itself will not be the same as the speed of the ship unless the wake has a speed of zero. If w = wake fraction, V = speed of ship, knots, V_a = speed of advance of propeller,

$$w = \frac{V - V_a}{V} \qquad \text{or} \qquad V_a = V(1 - w)$$

Thrust deduction is due to the propeller's drawing water past the surface or skin of the hull and thereby causing a backward drag. If the propeller were not there, this would not exist; consequently, it is not a regular part of the resistance such as would be evident or become evident in a towed test.

Thrust-deduction effect is specified as the thrust-deduction coefficient and is the ratio between the thrust deduction and the initial thrust of the propeller. If T = propeller thrust, lb, t = thrust-deduction coefficient, $(1 - t)$ = proportion of the propeller thrust useful in driving the ship,

$$T(1 - t) = \text{useful thrust}$$

$$T = \frac{326 \text{ ehp}}{(1 - t)V}$$

Hull efficiency is defined as

$$\frac{1 - t}{1 - w}$$

Therefore, it can be seen that, if the wake fraction is greater than the thrust deduction, the hull efficiency is greater than 100 percent.

$$\text{Ehp.} = U\left(\frac{1 - t}{1 - w}\right)$$

Therefore,

$$U = \frac{\text{Ehp}}{\dfrac{1 - t}{1 - w}} = e_p \text{ shp}$$

and

$$\text{Shp} = \frac{\text{ehp}}{e_p\left(\dfrac{1 - t}{1 - w}\right)}$$

From the foregoing it is obvious that, if values for ehp, w, t, V, and N are

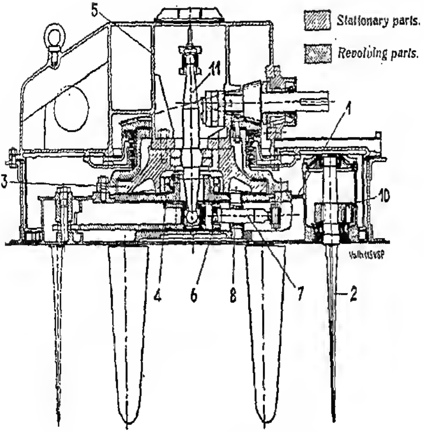

FIG. 15a.—Voith-Schneider propeller assembly.

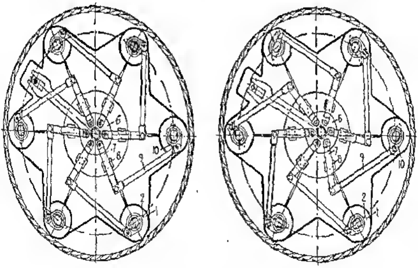

FIG. 15b.—Voith-Schneider propeller feathering motion.

values are determined from hull characteristics with the exception of N, the propeller designer should obtain them from the naval architect. N, of course, is determined by the marine engineer, and the propeller designer should obtain that value from him.

Cavitation. If the blade of a propeller of given blade area is driving a ship through water, a pressure exists on the driving face of the blade. For a given thrust on this part of the propeller the unit pressure will increase as the blade is made more narrow. At the same time, on the reverse side of the blade, the pressure is relieved; and, if the revolutions are sufficiently high and the slip sufficiently great, a partial vacuum may exist to the extent that vaporization of the water takes place and a conventional boiling of the water on the back of the blade is evident. The result of this is that the whole propeller may become enveloped in a boiling mass of water and thrust may no longer increase in the same proportion to the torque applied as was the case before this boiling started to occur. The energy put into the propeller shaft is going, to a great degree, to boiling water rather than to propelling the ship. This phenomenon is called cavitation and, from its nature, is more likely to occur under the following conditions:

1. *The Pitch Ratio Is Great.* If the pitch is small, the propeller more nearly approaches the condition of a disk rotating in the water, which would be the case were the pitch ratio zero. In this case, there would be no tendency to create a vacuum back of the blades and consequently no boiling. As the pitch is increased, this tendency to create the vacuum back of the blade grows greater with the allied tendency to boil.

2. *The Slip Is Great.* If there were no slip, the effect would be the same as that of a disk revolving in the water, as in the case of zero pitch; therefore, there could be no tendency toward a vacuum and consequently boiling.

3. *The Hub Depth Is Small.* The deeper the hub, the greater will be the pressure of water on the propeller and, consequently, the less the tendency toward a vacuum and consequent boiling.

4. *The Blade Area Is Small.* The smaller the blade area, the greater will be the unit pressure on the driving face and this greater tendency to cause vacuum on the back of the blade.

The foregoing characteristics refer to a propeller of given diameter. Since the speed of any portion of the surface for a given rpm is proportional to the diameter, it follows that the rpm at which cavitation will start is inversely proportional to the diameter.

Capt. E. F. Eggert, USN, developed a method for determining the approximate rpm at which cavitation will start. Among other factors, this method involves the thickness ratio of the blade section, or its maximum thickness divided by its width, where the maximum thickness is in the center as in the case of an ogival blade. Capt. Eggert called this ratio c. For the airfoil section where the maximum thickness is at about one-third the width from the leading edge, c is three-fourths the thickness ratio described above (see Figs. 7 and 8). Naturally, as the blade width is increased, the thickness increases; but, for all practical purposes in the case of ogival sections,

$$c = \frac{0.46 - 0.74b}{5.7}$$

where b = M.W.R.

For a given temperature the boiling pressure of water is the absolute pressure rather than the gage pressure. This can also be expressed in terms

assemblies per ship. The blades are caused to rotate about a vertical central axis; at the same time they feather or oscillate around their own axes. By changing the feathering angle, this being done from the bridge by fairly simple control devices, the thrust can be made to act in any direction, even in reverse. As a consequence, no rudder is needed. Also, this results in a highly maneuverable ship. They have not been built in powers greater than 2,500 shp. Claims for extraordinary efficiency are based on the fact that the rudder, struts, and other such appendages can be removed from the hull, thereby reducing the hull resistance. The actual efficiency of the blade arrangement is little different from that of the conventional propeller (see Figs. 14 and 15).

Example. In order to use the foregoing data and information, take the ship for which the effective horsepower was worked out on p 1397. The ehp = 3,324 (see p. 1399). Block coefficient, $C_p = 0.651$ (see p. 1383). Refer to the curve (Fig. 7) on p. 1406 and find the wake fraction, $w = 0.20$. The hull efficiency, e_h, for a twin-screw ship of conventional design should be approximately unity (see p. 1407).

$$e_h = \frac{1-t}{1-w} = 1.00 = \frac{1-t}{1-0.20}$$

$$t = 0.20$$
$$V = 14.25 \text{ knots}$$
$$H = 25.5 \text{ ft draft}$$
$$N = \text{rpm} = 100$$

$$U = \frac{\text{ehp}}{\dfrac{1-t}{1-w}} = \frac{3{,}324}{2\left(\dfrac{1-0.20}{1-0.20}\right)} = 1{,}662$$

$$U^{1/2} = 40.75$$
$$V_a = V(1-w) = 14.25(1-0.20) = 11.4$$
$$V_a^{5/2} = 439$$

$$B_u = \frac{NU^{1/2}}{V_a^{5/2}} = \frac{100 \times 40.75}{439} = 9.28$$

Since this value of B_u is such that the efficiency of either three- or four-bladed propellers will be the same (see Figs. 1 and 2), suppose a four-bladed propeller is chosen.

For maximum efficiency, $a = \frac{p}{d} = 1.00$ and $\delta = 131$

$$e_p = 0.695$$

$$d = \frac{\delta V_a}{N} = \frac{131 \times 11.4}{100} = 14.95 \text{ ft, call it 15 ft}$$

All this is on a basis of M.W.R. = 0.25 and B.T.F. = 0.05. This to be checked for cavitation.

$$\text{rpm}_c = \frac{60}{d}\sqrt{\frac{h[7.3(1+4b)]}{aS+5.7c}}$$

Since the draft, H, is 25.5 ft, the hub depth could be 17.5 ft.

$$h = 33 + 17.5 = 50.5$$
$$5.7c = 0.46 - 0.74b = 0.275$$

of feet head of water. Atmospheric pressure in terms of feet head is 33 ft. Since the absolute pressure on the propeller blades is the depth of water plus the atmospheric pressure on the surface of the water, the absolute head is

$$h = 33 + \text{depth in ft}$$

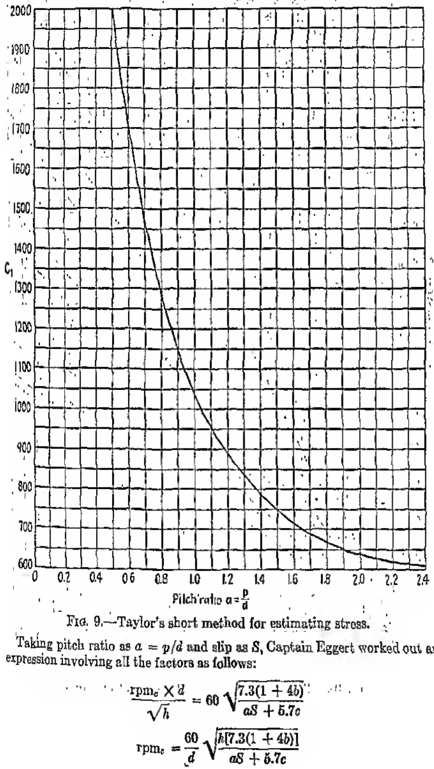

Fig. 9.—Taylor's short method for estimating stress.

Taking pitch ratio as $a = p/d$ and slip as S, Captain Eggert worked out an expression involving all the factors as follows:

$$\frac{\text{rpm}_c \times d}{\sqrt{h}} = 60\sqrt{\frac{7.3(1 + 4b)}{aS + 5.7c}}$$

$$\text{rpm}_c = \frac{60}{d}\sqrt{\frac{h[7.3(1 + 4b)]}{aS + 5.7c}}$$

$$1 - S = \frac{101.33}{a\delta} = \frac{101.33}{1.00 \times 131} = 0.774$$

$$S = 0.226$$

$$\text{rpm}_c = \frac{60}{15}\sqrt{\frac{50.5(7.3 \times 2)}{0.226 + 0.275}} = 153 \text{ which is higher than necessary.}$$

Try M.W.R. = 0.20

$$\text{rpm}_c = \frac{60}{15}\sqrt{\frac{50.5(7.3 \times 1.8)}{0.226 + 0.312}} = 140$$

This is more than enough margin for safety and there is little, if anything, to be gained in the way of efficiency by reducing the blade width further.

Check for strength (see Figs. 9 and 10)

$$c_1 = 1{,}040, \quad X = \frac{c_1 P_1}{N d^3}$$

The power per propeller will be approximately $\dfrac{3{,}324}{2 \times 0.695} = 2{,}395$

$$P_1 = \frac{2{,}395}{4} = 598$$

$$X = \frac{1{,}040 \times 598}{100 \times 15^3} = 1.84$$

$$Y = \tfrac{2}{3}\,(\text{M.W.R.})\,(\text{B.T.F.})^2 = 0.00036 \text{ for } 5{,}000 \text{ psi.}$$

$$\tfrac{2}{3}(0.20)(\text{B.T.F.})^2 = 0.00036$$

$$\text{B.T.F.} = 0.052$$

Correct for δ and e_p (see Fig. 3).

$$\delta \text{ corrected} = 131 \times 0.995 = 130$$

$$e_p \text{ corrected} = 0.695 \times 1.00 = 0.695$$

Consequently, from an efficiency standpoint it would be just as well to retain the M.W.R. = 0.25 and B.T.F. = 0.05 and there would be a gain in strength.

Check for strength.

$$X = 1.84$$

$$Y = \tfrac{2}{3}(0.25)(0.05)^2 = 0.000416$$

Stress approximately 4,000 psi

$$\text{shp} = \frac{\text{ehp}}{e_p\left(\dfrac{1-t}{1-w}\right)} = \frac{3{,}324}{2 \times 0.695} = 2{,}395 \text{ per shaft.}$$

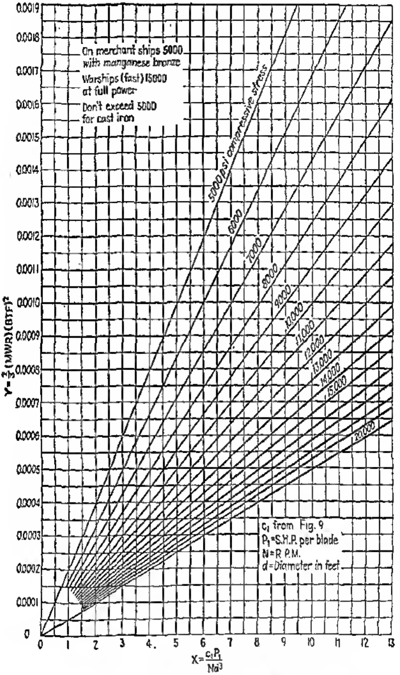

FIG. 10.—Taylor's short method for estimating stress.

PROPULSION SHAFTING

BY

AUSTIN H. CHURCH and J. M. LABBERTON

REFERENCE: Den Hartog, "Mechanical Vibrations," McGraw-Hill.

General. Shafting, being long, is invariably made up of several sections, which are fastened together inside the ship by means of conventional flanged couplings. The flanges are formed by upsetting the ends of the shafts and are, therefore, forged integrally therewith. Either parallel bolts with heads and a slight clearance between the body of the bolt and the hole may be used, or tapered bolts without heads that completely fill the hole. In the latter case the two flanges should be reamed and tapered together with a taper of ¾ in. to the foot. This makes an excellent joint but there is no interchangeability. If it is taken down, it should be reamed again.

Shear stress in the bolts should not exceed 8,500 psi for high-speed vessels where the material has an ultimate tensile strength of 120,000 psi, nor should it exceed 5,000 psi on merchant ships where the material has an ultimate tensile strength of 60,000 psi. In addition to shear stresses there are, of course, tension stresses due to any bending of the assembled shafting. The bolt sizes are usually fixed by classification society rules. Generally the bolt material has the same physical characteristics as the shafting.

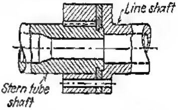

FIG. 1.—Inboard shaft coupling.

A coupling such as shown in Fig. 1 is usually fitted just inboard of the stern tube. Such a coupling will transmit ahead and astern thrust and torque. Often it is desirable to pull the stern-tube shaft out through the stern-tube

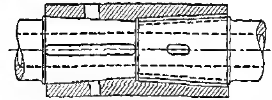

FIG. 2.—Outboard shaft coupling.

bearing in order to make repairs. This is much more convenient than taking the shaft into the hull and shaft alley and out through the engine room. It can be done with the coupling such as shown in Fig. 1. The stern-tube shaft has the same diameter all the way through. During astern operation the load is taken by a collar held in place by bolts as shown. Outside the ship where the shaft is exposed to the sea, couplings such as shown in Fig. 2 are generally used. Note that keys are used across the diameters to prevent the shaft sections from pulling out of the tapers when the ship is backing. One advantage of this type of coupling is that it offers less resistance to water flow than would a conventional flange coupling.

where rpm_c is the predicted rpm at which cavitation will start. It will be noted from this expression that high pitch ratio, slip, and diameter lower the speed at which cavitation will start and that the deeper the propeller works in the water and the wider the blade, the higher the speed that can be attained before cavitation will start.

Hub depth is the depth considered, for this is the average depth of the blades.

Strength. To calculate the blade stresses in propellers under conditions of load is a complicated and involved procedure. However, in order to obtain a quick, if not too accurate, estimate of the strength of a propeller,

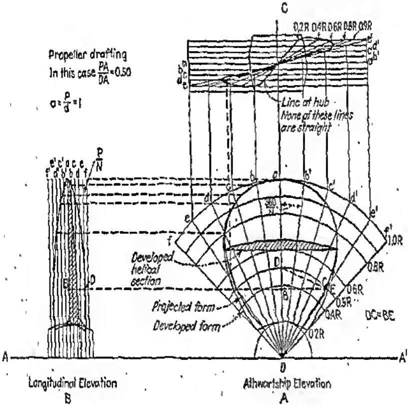

FIG. 11.—Drafting of propellers.

Admiral Taylor drew some curves through points indicating the strength of a number of propellers. By means of these curves, it is possible to determine quickly the maximum compressive stress approximately. These curves are shown in Figs. 9 and 10.

Drafting of Propellers. The object in making a drawing of a propeller is to obtain a visual idea as to how it would appear, to obtain clearance dimensions with the hull, and to furnish the patternmaker and machinist with sufficient information to manufacture the propeller properly. The drafting of propellers is fairly simple provided that the geometry is thoroughly understood. There are several methods of depicting propellers. The one that will now be demonstrated has proved satisfactory in practice.

Sometimes it is necessary to incline the blades of a propeller in order to clear the ship's rudder or other stern parts. In this event, the surface of a

Stresses. As regards the shafting proper, it must withstand combined torsional, bending, and thrust stress. Also the flexural and torsional critical speeds must be out of the range of normal operating speeds. Finally the classification society rules must be met.

Torsional stress is caused by the twisting moment. In the case of geared-turbine or electric drive the torque is fairly smooth but, in the case of reciprocating-engine drive, steam or diesel, the torque pulsates or rises and falls in

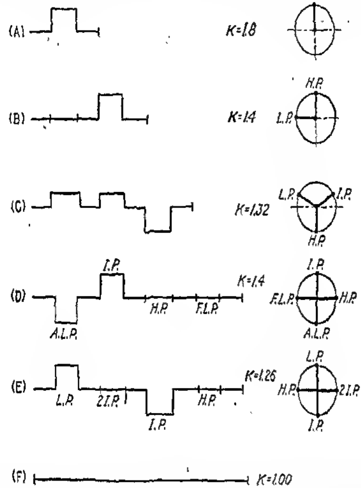

FIG. 3.—Values of K for shafting driven by reciprocating steam engines.

magnitude. Naturally the shaft must withstand the maximum stress. The twisting moment in inch-pounds is

$$M_T = \frac{\text{shp}}{\text{rpm}} \times 63.024 \times K$$

where K is a factor depending on the number of cylinders and crank arrangements of the reciprocating engine. In the case of geared-turbine or electric drive, K is unity. The value of K for various steam-engine arrangements is shown in Fig. 3. If the ihp only is known, a mechanical efficiency of 92 percent may be assumed, in which case

$$M_T = \frac{\text{ihp}}{\text{rpm}} \times 57{,}980 \times K$$

screw is generated by a straight line moving forward at a certain rate, rotating about a fixed axis, and inclined at a fixed angle to the axis of rotation. In most cases, however, the surface is generated by a straight line moving forward at a certain rate, rotating about a fixed axis, and vertical to the fixed axis. The former is called an **inclined generatrix** and the latter a **vertical generatrix**.

Propellers having a vertical generatrix will be considered first. Let R be the radius of the propeller, which in this case is unity. In any practical case the actual diameter should be used. However, it would be more convenient to continue to consider the even percentages of the radius for determining the blade sections, as will be demonstrated. Draw radial lines ob, ob', etc., forming equal angles at o (Fig. 11A).

$$N = \text{number of equal angles for a complete circle}$$
$$p = \text{pitch of propeller}$$
$$\frac{360}{N} = \text{degrees in each equal angle}$$

Draw arcs with radii of $0.2R$, $0.3R$, etc. Plot projected form of blade by means of proportions given in Fig. 6.

Projection on Longitudinal Plane (Fig. 11B). Draw axes as before. Draw vertical lines spaced p/N apart and letter a, b, c, etc. Project points of intersection of projected form with the radial lines of Fig. 11A over to Fig. 11B. The points where these projection lines intersect corresponding lettered lines are points of longitudinal projected form as shown on Fig. 11B.

Plan (Fig. 11C). Draw axis a, a_1. Draw horizontal lines spaced p/N apart, and letter b, b', etc. Project points of intersection of radial lines with arcs $0.2R$, $0.3R$, etc. (Figs. 11A to 11C). The intersections of these projection lines and the corresponding horizontal lettered lines (Fig. 11C) are points of helices, $0.2R$, $0.3R$, etc. Project points of intersection of projected form with arcs (Figs. 11A to 11C). The intersections of these projection lines and the corresponding lettered helices are points of plan projected form as shown in Fig. 11C.

Developed Form (Fig. 11A). Take any arc as $0.5R$ and draw a horizontal line BC through its intersection with the projected form. Extend this line to the longitudinal section (Fig. 11B) and obtain BD. Transfer BD to the athwartship elevation (Fig. 11A) to axis oa. Draw DC. With DC as a radius and B as a center, draw an arc intersecting BC projected. This intersection is a point on the developed form, E.

In the case of the **inclined generatrix** the procedure is exactly the same except that in the longitudinal elevation the lines a, b, c, d, etc., are inclined to the right or left, as the case may be, at the proper angle but spaced apart horizontally a distance equal to p/N. Correction must be made for this inclination in the plan view by inclining, from which $0.2R$, $0.4R$, $0.6R$, etc., are drawn.

Blade Sections. In the case of an ogival blade the section is formed by a straight line and an arc; in the case of a streamlined blade, by a series of curves. For the sake of simplicity, consider an ogival section as shown in Fig. 11A, but bear in mind that this section can be replaced by a streamlined one. In any case, the length of the blade section is

$$\text{Length} = \sqrt{(\text{circumference})^2 + (\text{pitch})^2} \times \frac{\text{angle}}{360}$$

In the case of diesel engines with direct-drive, the following values of K should be used.

$$M_T = \frac{\text{ihp}}{\text{rpm}} \times 50{,}420 \times K \quad \text{(attached auxiliaries)}$$

$$M_T = \frac{\text{ihp}}{\text{rpm}} \times 53{,}867 \times K \quad \text{(independent auxiliaries)}$$

	Cylinders	Value of K
4-cycle single-acting	1 4 6 8 10 12	17 2.3 1.6 1.38 1.24 1.15
2-cycle single-acting	2 3 4 6	3.48 2.10 1.38 1.15
4-cycle double-acting	2 3	1.38 1.15

Calculation of Stresses. The line shaft is subjected to three primary stresses which act simultaneously: (1) torsion, due to the driver f_s, (2) direct compression, due to the propeller thrust f_t, and (3) bending, due to its own weight, f_b.

A more effective use of the material for bending and torsional strength from a weight standpoint may be obtained by using a hollow shaft. For this reason propulsion shafting is often made hollow with the inside diameter about 60 percent of the outside.

The transmitted torque, M_T, in inch-pounds will induce a torsion or shear stress of magnitude

$$f_s = \frac{5.1 M_T D}{D^4 - d^4}$$

where D = outside diameter of the shaft, in.
d = inside diameter, in. If the shaft is solid, d equals zero.

The propeller thrust, T lb, may be found from the equation

$$T = \frac{326 \text{ ehp}}{(1 - t)V}$$

where ehp = effective horsepower
t = thrust-deduction coefficient (see p. 1419)
V = speed of the ship, knots

The action of this thrust may produce a column effect in the shaft, particularly if the ratio of bearing span to shaft diameter is large. This is included in the

The angle is at o between radii through the intersection of the projected form and the arc at the radius at which the blade section is to be determined. Calculate the length as outlined above, project over to the longitudinal section to obtain the blade thickness at that point, and the section is known.

Noise. Propeller noise is usually caused by the propeller tips being too close to the hull, which causes the hull to vibrate, or by the leading edges of the blade being too blunt. Propeller blade tips in general should not swing within 24 in. of the hull plating. Also, too few blades sometimes are the cause of synchronous vibrations. The greater the number of blades, the greater the frequency at given rpm (see p. 1436).

Bad propeller whine, or "singing," has been cured merely by sharpening the leading edges of the blades.

Weights. A quick approximation of propeller weight can be determined from the expression

$$\text{Weight, lb} = Kd^3(\text{M.W.R.})(\text{B.T.F.})$$

where K = 345 for three blades
K = 450 for four blades

$$\text{Radius of gyration} = 0.21d$$

where d = diameter, ft.
The above values of K are for bronze propellers. If another material is used, correction must be made for the density.

Backing of Propellers. In the case of any propeller, the thrust is a function of the torque. The exact relationship is uncertain but model-basin tests indicate that when propelling forward, the driving being done by the face of the blades,

$$\frac{Td}{Q} = 8 \text{ approx}$$

But when revolving backward, the driving being done by the backs of the blades,

$$\frac{Td}{Q} = 5.5 \text{ approx}$$

where Q = torque, lb-ft

When a ship is proceeding forward with the propeller operating normally, driving is done by the face of the propeller blades and there is slip. If the torque on the propeller is reversed, the slip first goes to zero. While going to zero, the thrust is still forward until the slip reaches zero at which instant the thrust is zero. This is the normal forward operation of a propeller.

This is followed by a second period during which the slip becomes negative and gradually increases negatively until the rpm is zero. During this period the thrust has reversed although the propeller continues to turn in the forward direction. At approximately the point of zero rpm erratic behavior of both torque and thrust may be expected. This may be due to a cavitation phenomenon but it is not certain. In any event, the propeller at this instant is dragged through the water by the ship and the effect is as if the propeller an appendage fastened firmly to the stern.

en a third period or phase of operation begins when the propeller, owing e reverse torque, starts to turn or revolve in reverse and then increases n until the ship comes to rest in the water and is traveling at zero knots.

equation

$$f_t = \frac{T}{A}\left[1 + \frac{16L^2}{25{,}000(D^2 + d^2)}\right]$$

where A = cross-sectional area of the shaft, sq in.
L = distance between the bearing centers, in.

Since the shaft is supported on many bearings, the bending action is similar to that of a uniformly loaded continuous beam, and the bending moments should be calculated on that basis. However, it is generally sufficiently accurate to treat each span as though it were a beam with fixed ends and a distributed load. The distributed load is that due to the weight of the shaft. On this latter basis, the maximum bending stress is given by the equation

$$f_b = \frac{0.849wL^2D}{D^4 - d^4}$$

where w = shaft weight per in. of length, lb

These primary stresses may be combined to obtain the resultant shear and compressive stresses by the standard formulas

$$f_t' = \tfrac{1}{2}(f_t + f_b) + \tfrac{1}{2}\sqrt{(f_t + f_b)^2 + 4f_s^2}$$
$$f_s' = \tfrac{1}{2}\sqrt{(f_t + f_b)^2 + 4f_s^2}$$

Generally there is no bearing placed aft of the propeller. In such cases this section is overhung and a cantilever action takes place. The bending stress is then due to the weight of the propeller itself plus the distributed weight of the overhung shaft. The bending moment, when the ship is lying idle in calm water, is the weight of the propeller with its nut, etc., multiplied by the shaft length from the after-strut bearing to the propeller-assembly center of gravity plus the relatively slight moment due to the stub end of the shaft weight.

When the ship is at sea under storm conditions, there will be additional inertia stresses due to the sudden accelerations and decelerations as the ship pitches and yaws. Since it is impossible to predict the exact magnitude of these stresses, it is common practice to design by doubling the bending moment due to the propeller assembly weight alone, i.e., let the moment $M_B = 2F_1L_1$ where F_1 is the impeller assembly weight and L_1 is the distance from the after-strut bearing to the center of gravity of the propeller assembly in inches.

The primary stresses, which can be combined as noted for the previous case, become

$$f_b = \frac{10.2M_BD}{D^4 - d^4}$$

$$f_t = \frac{T}{0.7854(D^2 - d^2)}$$

$$f_s = \frac{5.1M_TD}{D^4 - d^4}$$

A fourth period or final phase of operation begins when the ship starts to back or make sternway. This continues until a steady state of ship-speed astern, and astern or reverse rpm is attained.

These four phases may be summarized as follows:

1. Negative torque; positive rpm; positive knots; positive slip; positive thrust. Ending in zero slip.

2. Negative torque; positive rpm; positive knots; negative slip; negative thrust. Ending in zero rpm.

3. Negative torque; negative rpm; positive knots; negative slip; negative thrust. Ending in zero knots.

4. Negative torque; negative rpm; negative knots; negative slip; negative thrust. Ending in a fixed backing speed.

In a manner similar to that in which $B_u = \frac{NU^{1/2}}{V^{5/2}}$ was shown to hold constant for any value of Nd/V, it can be shown that T/V^2d^2 is constant as well as Q/V^2d^3 is constant. This being true, a model propeller of the proper

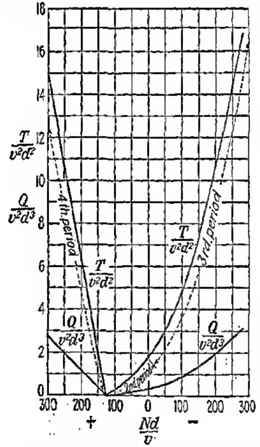

FIG. 12.—Performance of propeller in reverse or backing.

proportions can be run in reverse in a water tunnel and the data from this test plotted as shown in Fig. 12. This curve can then be used to determine the thrust and torque at a given speed of motion backward through the water

It has been observed that for some ships there is a rise and fall in the torque on the propeller shaft due to the proximity of the propeller blades to the hull of the ship. For ordinary clearances encountered in present-day design this pulsating torque amounts to approximately $7\frac{1}{2}$ percent of the average torque carried by shaft in ships having a rounded stern. For propellers operating closely behind a strut or skeg, this pulsation may amount to 15 percent of the mean torque.

Stress Concentration. So far no mention has been made of increased stresses due to stress concentration brought about by small-radii fillets at points where the shaft section changes, as, for instance, where flanges are made for couplings. Methods for allowing for this are shown on p. 420. The greater the change in diameter and the smaller the radius of the fillet, the greater the concentration of the stress at the point of the fillet, amounting to as much as five times the stress in other parts of the member.

Bearings. There must be bearings both inside the hull and outside exposed to the sea. The bearings inside are usually oil-ring-lubricated and babbit-lined such as are used on most slow-speed industrial rotatingapp aratus (see p. 873).

The bearings outside the hull are lubricated by the water that surrounds them and goes through them. The forward stern-tube bearing receives its lubricating water usually from the general service pump in the ship; however, sometimes, the packing gland is loosened and water is permitted to flow in from the sea through the bearing, this water later being discharged overboard by the bilge pumps. The bearing consists of longitudinal strips of wood (lignum vitae blocks with grain on edge) driven into grooves, rubber-bearing surfaces vulcanized to brass backing strips which are driven into the grooves, or phenolic composition blocks made up of cloth and plastic driven into the grooves. The friction losses in these bearings are negligible.

One virtue claimed for the rubber is that if sand or small stones are drawn into the bearing, the rubber will flex and the foreign matter will roll right out; in the case of wood or fabric-plastic, the stones would become embedded and score the shaft.

Thrust bearings are mounted just aft of the engine in a separate casing on reciprocating-engine drive; in the case of geared-turbine drive, they are in the gear box (see p. 1444). The horseshoe type is rarely used except on old installations, having been superseded by the Kingsbury or Michell type. Constructional details and operational characteristics of these bearings are shown on p. 875.

Torsional Vibration. After the moving masses and the interconnecting shafts of a marine drive have been tentatively designed, it is necessary to determine the natural torsional frequencies of the system. The frequencies of the disturbing impulses imposed either by the propeller (number of blades times the propeller rpm) or the driving engine should not equal the natural frequency or whole multiples of it. If this precaution is not observed, resonant conditions may develop which will cause severe strains on the system, shock loading on the gear teeth, or fatigue failures of the shafting. If resonance seems probable, the sizes of the various parts should be altered to avoid this condition.

In determining the natural frequencies of vibration, the positions of the nodes may also be located. Frequently the drive is designed to secure a **nodal drive,** *i.e.*, have a node located at the gear. This will reduce the dynamic impulses on the gear teeth due to the vibration.

$A = BX$. This point X is called the **quotient,** A divided by B, and is denoted by A/B (where $B \neq 0$). Thus, the point A/B is a point whose angle is the angle of A minus the angle of B, and whose distance is the distance of A divided by the distance of B. The point U/B ($B \neq 0$) is called the **reciprocal** of the point B, and is denoted by $1/B$. (See Fig. 5.) With these definitions of AB and A/B the elementary laws of multiplication and division that hold in the algebra of real numbers hold also in the algebra of complex quantities. In particular, the point U has all the formal properties of the number unity, and is denoted by 1.

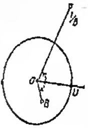

FIG. 5.

[Note: If A and B are real, AB and A/B will also be real.]

Repeated Multiplication. Powers and Roots. The point $A \times A \times A \times \ldots \times A$ to n factors is called the nth power of A and is denoted by A^n (Fig. 6). Conversely, if any point A (not 0) and any positive integer n are given, there will be n distinct points X such that $X^n = A$; each of these points is called an **nth root of A**, some one of them, usually the one with the smallest positive angle, being denoted by $\sqrt[n]{A}$ or $A^{1/n}$. Thus, the point $\sqrt[n]{A}$ is a point whose distance is the nth root of the distance of A, and whose angle is $1/n$th of the angle of A. All the nth roots of A will lie on the circumference of a circle about O as center, and will divide that circumference into n equal parts (Fig. 7). Every point A (not 0) has two square roots, three cube roots, etc. Hence the theorem "If $A^n = B^n$ then $A = B$" does not hold in this algebra, and the ordinary rules for radical signs must be applied with caution. For example, if A and B are positive reals, $\sqrt{-A}\cdot\sqrt{-B} = -\sqrt{AB}$ and not $\sqrt{(-A)(-B)}$, which would give $+\sqrt{AB}$.

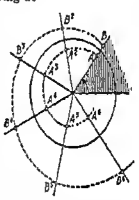

FIG. 6.

[Note: If A is real and positive, $\sqrt[n]{A}$ will be real and positive; if A is real and negative, $\sqrt[n]{A}$ will be real if n is odd and imaginary if n is even.]

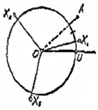

FIG. 7.

Properties of i. The *point i is the point whose distance is 1 and whose angle is 90 deg.* It follows from the definition above that **multiplying any point A by i has the effect of rotating the point through an angle of $+90°$** without changing its distance from O. In particular,

$i^2 = -1$, $i^3 = -i$, $i^4 = 1$, $i^5 = i$, etc.; $i = \sqrt{-1}$, $-i = -\sqrt{-1}$; where "1" denotes not the *number* one, but the *point* U.

Similarly, multiplying any point A by -1 has the effect of rotating the point through 180 deg.

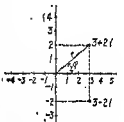

FIG. 8.

First Standard Form for a Complex Quantity (Fig. 8). Any point A can be expressed in the form $x + iy$, where x and y are real points. For example, the three cube roots of 1 are 1, $-\frac{1}{2} + \frac{1}{2}i\sqrt{3}$, and $-\frac{1}{2} - \frac{1}{2}i\sqrt{3}$.

In general, $(x_1 + iy_1) + (x_2 + iy_2) = (x_1 + x_2) + i(y_1 + y_2)$;
$(x_1 + iy_1)(x_2 + iy_2) = (x_1x_2 - y_1y_2) + i(x_2y_1 + x_1y_2)$;

$$\frac{x_1 + iy_1}{x_2 + iy_2} = \frac{x_1x_2 + y_1y_2}{x_2^2 + y_2^2} + i\,\frac{x_2y_1 - x_1y_2}{x_2^2 + y_2^2}.$$

If two complex quantities are equal, their real parts must be equal, and the coefficients of their pure imaginary parts must also be equal. That is, if $x_1 + iy_1 = x_2 + iy_2$, then $x_1 = x_2$ and $y_1 = y_2$. Thus a single equation between complex quantities is equivalent to two equations between real quantities.

Conjugate Imaginaries. Two points $A = x + iy$ and $B = x - iy$ are called conjugate imaginaries. Two such points are symmetrically situated with regard to the axis of reals. The sum and product of two conjugate imaginaries will be real.

Second Standard Form for a Complex Quantity. Since $x = r\cos\varphi$ and $y = r\sin\varphi$, any point $A = x + iy$ can be expressed $A = r(\cos\varphi + i\sin\varphi)$, where r is real and positive (namely, the distance of A), and φ is real (namely the angle of A). For example, the three cube roots of 1 are 1, $\cos 120° + i\sin 120°$, and $\cos 240° + i\sin 240°$. In general,
$[r_1(\cos\varphi_1 + i\sin\varphi_1)][r_2(\cos\varphi_2 + i\sin\varphi_2)] = r_1r_2[(\cos(\varphi_1+\varphi_2) + i\sin(\varphi_1+\varphi_2)]$;
$[r(\cos\varphi + i\sin\varphi)]^n = r^n[\cos(n\varphi) + i\sin(n\varphi)]$ **(De Moivre's Theorem).**

The Exponential Function, e^A, or $\exp A$, of any point $A = x + iy$ is defined as the point whose distance is e^x and whose angle (measured in radians) is y. That is, $e^{x+iy} = e^x(\cos y + i\sin y)$. Here e^x means the ordinary exponential function of the real quantity x, where $e = 2.718$.

From this definition, the usual formal laws of exponents can be deduced: $e^Ae^B = e^{A+B}$, $(e^A)^n = e^{nA}$, $e^{-A} = 1/e^A$; $e^1 = e$, $e^0 = 1$.

The function e^A is a periodic function with a pure imaginary period $2\pi i$; that is, $e^{A \pm k2\pi i} = e^A$, where k is any positive integer.

If A is made to move along a line parallel to the axis of reals [or axis of pure imaginaries], the corresponding point e^A will move along a straight line through O [or along a circle about O as center].

Properties of $e^{i\varphi}$. The point $e^{i\varphi}$ is a point whose distance is 1 and whose angle is φ. It follows from the definitions above that **multiplying any point A by $e^{i\varphi}$ has the effect of rotating the point through an angle** φ, without changing its distance from O. In particular, $e^{i\pi} = -1$, $e^{-i\pi} = -1$; $e^{i\pi/2} = i$; $e^{-i\pi/2} = -i$; $e^{2\pi i} = 1$.

Third Standard Form for a Complex Quantity. Any point A can be expressed in the form $A = re^{i\varphi}$, where r is the distance and φ the angle of the point. For example, the three cube roots of 1 are 1, $e^{\frac{1}{3}2\pi i}$, $e^{\frac{2}{3}2\pi i}$. In general,

$$(r_1e^{i\varphi_1})(r_2e^{i\varphi_2}) = (r_1r_2)e^{i(\varphi_1+\varphi_2)};\quad (re^{i\varphi})^n = (r^n)e^{in\varphi}.$$

If $x + iy = re^{i\varphi}$, then $r = \sqrt{x^2 + y^2}$, $\sin\varphi = \dfrac{y}{r}$, $\cos\varphi = \dfrac{x}{r}$, $\tan\varphi = \dfrac{y}{x}$.

If two complex quantities are equal, their distances will be equal, and their angles will differ at most by some multiple of 2π. Thus, if $r_1e^{i\varphi_1} = r_2e^{i\varphi_2}$ then $r_1 = r_2$ and $\varphi_1 = \varphi_2$ or $\varphi_2 \pm k2\pi$. Here again a single equation between complex quantities is equivalent to two equations between real quantities.

Equivalent Systems. Many marine systems employ gears between the driver and propeller so that each may operate at its most efficient speed. Since the frequency calculation is based upon the energies stored in the masses and shafts and since these are proportional to the square of the speed of rotation, it is necessary to correct the actual values of inertia and spring scale to that of an equivalent system operating at an equivalent speed (usually that of the propeller). The equations for conversion are

$$\text{Equivalent spring scale, } k_{eq} = k_{act}\left(\frac{\text{actual speed}}{\text{equivalent speed}}\right)^2$$

$$\text{Equivalent inertia, } I_{eq} = I_{act}\left(\frac{\text{actual speed}}{\text{equivalent speed}}\right)^2$$

The inertia of a mass may be found by summing up the product of the weight and the radius of gyration squared of each of the component parts and dividing the result by g, the acceleration of gravity. These values are generally furnished by the manufacturer of the part concerned. The actual inertia of the propeller is usually increased by 20 percent to allow for the entrained water which must move with it. The inertia of the shaft is generally accounted for by taking one-third of it and considering this to act with the adjacent mass. It can be shown that this procedure is theoretically correct.

The shaft-spring scale between the masses is given by $k = \dfrac{G}{L_{eq}}\dfrac{\pi d_{eq}^4}{32}$, where G is the shearing modulus of elasticity of the material (12,000,000 for steel), L_{eq} is the equivalent length of the shaft in inches having an equivalent diameter d_{eq} in. Since the shafts are always stepped, it is convenient to refer the various lengths and diameters to one equivalent diameter (usually 1 in.) before the spring scale is found. The corresponding equivalent length, L_{eq}, is one that will give the same deflection for a given torque as the actual shaft. Thus to determine the equivalent length of shaft, $L_{eq} = L_{act}\left(\dfrac{d_{eq}}{d_{act}}\right)^4$ or if the equivalent shaft diameter is 1 in., $L_{eq} = L_{act}/d_{act}^4$. The sum of the equivalent lengths between the masses is used in the spring-scale equation given above. The equivalent length of crankshafts is given on p. 514.

Frequency Determination. If the system can be approximated by two or three masses connected by shafts, the frequencies may be found by the equations given on pp. 513 and 514. Generally such approximations are avoided for the final determination, the frequencies, nodes, and amplitudes being calculated in tabular form by the Holzer method (Holzer, "Die Berechnung der Drehschwingungen").

The Holzer method is based upon the principle that, at the natural frequency, the inertia and elastic torques of the system are in equilibrium; *i.e.*, the sum of the inertia torques of the system equals zero when it is vibrating at the natural frequency. If I_1, I_2, etc., are the mass moments of inertia of the various masses, β_1, β_2, etc., are the corresponding maximum amplitudes of these masses, and ω is the natural frequency in radians per second, then $(I_1\beta_1 + I_2\beta_2 + \text{etc.})\omega^2 = 0$. The amplitude of an end mass is assumed to be 1 radian, and the other amplitudes are found in relation to this amplitude by considering the inertia and elastic torques; thus $\beta_2 = \beta_1 - I_1\omega^2\beta_1/k_1$, where

If the helix angle is considered and the approximate profile error is known, the second method may be used.

$$F_d = \frac{0.05V(F_t + LC\cos^2\psi)\cos\psi}{0.05V + (F_t + LC\cos^2\psi)^{1/2}} + F_t$$

where C is a factor dependent upon the tooth form, materials, and is directly proportional to the error. For a steel pinion and gear with an error of 0.001 in., C is 1,600 for 14½-deg teeth, 1,660 for 20-deg full-depth teeth, and

Table 1. Values of Form Factor y Based on Virtual Number of Teeth

N_v	14½ deg, composite and involute	20 deg, full depth	20-deg stub

Rack	0.210	0.262	0.280

1,720 for 20-deg stub teeth. As noted above, C is directly proportional to the error. The maximum error to be expected for hobbed and ground teeth is a function of the tooth size and is approximately:

Diametral pitch........	1	2	3	4	5	6 and finer
Max error, in..........	0.0012	0.0010	0.0008	0.0007	0.0006	0.0005

To avoid surface fatigue failures, the ability of teeth to wear well should also be investigated. The limiting load for wear is

$$F_w = D_p LKQ/\cos^2\psi$$

k_1 is the torsional spring scale between masses I_1 and I_2. A frequency ω is assumed that will satisfy the above basic equation, and the various amplitudes calculated. If the assumed frequency is not correct, the torque summation will not equal zero, and another assumption must be made. Thus the solution is a trial-and-error one and can be worked best in tabular form. After the correct frequency is found, the amplitudes β may be plotted at the various masses to locate the nodes. The process is best illustrated by an example.

Example. Consider a four-cylinder marine diesel engine with a flywheel driving a propeller as shown schematically in Fig. 4*a*. The values of the inertias and spring scales of the shafts are given on the figure. A circular frequency of 24.5 radians per sec is assumed ($\omega^2 = 600$) and Table 1 is set up.

The inertias are listed in the second column and are multiplied by the constant value of ω^2, which is 600, in the third. The spring constants of the shafts are listed in the

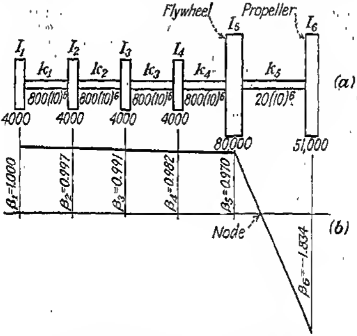

FIG. 4.—*Example of frequency determination.*

seventh column. Mass 1 is assumed to have an amplitude of 1 radian (top line of fourth column), hence the inertia torque of this mass is $I_1\omega^2\beta_1$ or $2.40(10)^6$. Dividing this by the spring constant k_1 of $800(10)^6$ gives the shaft deflection between masses 1 and 2 (top line of last column). If this value of 0.003 radian is subtracted from β_1, the value of β_2 which is 0.997 radian is obtained (second line of fourth column). The consequent inertia torque of mass 2 is $I_2\omega^2\beta_2$ or $2.39(10)^6$. The total torque acting on the shaft between masses 2 and 3 is the sum of the inertia torques of masses 1 and 2 since they act simultaneously in the same direction. This value is $4.79(10)^6$ as given in the second line of the sixth column. The deflection in the latter shaft is calculated, and the amplitude of mass 3 found. The process continues in this manner until the last mass (propeller) is reached. The algebraic sum of the inertia torques for the whole system should equal zero.

In the example, the remainder is $-0.03(10)^6$ which is negligibly small compared to the torques involved. Since this is so, the assumed frequency must be the correct one, and the first natural frequency is $24.5 \times 60/2\pi = 234$

where $Q = 2N_g/(N_g + N_p)$

N_g and N_p = numbers of teeth on gear and pinion, respectively

K = factor based upon the profile shape, material, surface hardness, and surface endurance limit (see Table 2)

If the original Brinell number of the gear is less than 180, it may be assumed that it will be increased to that value by the work-hardening effect of the pinion.

To secure satisfactory operation of the gears, the load acting on the teeth including the dynamic effects, F_d, must be less than the endurance strength, F_s, and wearing ability, F_w.

Table 2. Values of Coefficient K

Brinell No. of pinion	Brinell No. of gear	K for 14½-deg teeth	K for 20-deg teeth
150	150	30	41
200	150	43	58
250	150	58	79
200	200	58	79
250	200	76	103
300	200	96	131

Example. To check the design of the first reduction gears connected to the high-pressure turbine. Data: power 4,250 hp; pinion speed 4,960 rpm; gear speed 643 rpm; solid pinion diameter $D_p = 9.5$ in.; gear diameter $D_g = 73.33$ in.; pinion has two bearings with a 1½-in. gap between the helices; number of pinion teeth $N_p = 57$; number of gear teeth $N_g = 440$; 20-deg stub teeth; Brinell number of pinion teeth = 225, of gear teeth = 175; normal diametral pitch $P_{dn} = 7$; diametral pitch $P_d = 6$; helix angle $\psi = 31$ deg; active face width $L = 20$ in.

Factors of numbers of teeth:

Gear, $2^3 \times 5 \times 11 = 440$ teeth

Pinion, $3 \times 19 = 57$ teeth

Since there are no common factors, the numbers of teeth are satisfactory.

Lateral Deflection:

$$\frac{L + \text{gap}}{D_p} = \frac{20 + 1.5}{9.5} = 2.26 \text{ (less than 2.5, so satisfactory)}$$

Torsional Deflection:

$$t = \frac{0.013 \text{ hp } L}{nD_p^3} = \frac{0.013 \times 4{,}250 \times 20}{4{,}960 \times 9.5^3} = 0.00026 \text{ in. (less than 0.001 in., so satisfactory)}$$

Pitch Line Speed:

$$V = \frac{\pi Dn}{12} = \frac{\pi 9.5 \times 4{,}960}{12} = \frac{\pi 73.33 \times 643}{12} = 12{,}330 \text{ fpm}$$

Transmitted Load:

$$F_1 = \frac{33{,}000 \text{ hp}}{V} = \frac{33{,}000 \times 4{,}250}{12{,}330} = 11{,}370 \text{ lb}$$

cycles per min. The values of the relative amplitude β of the various masses as found in the fourth column are plotted on Fig. 4*b*. The node is located at the point of zero amplitude between masses 5 and 6. Its axial position is proportional to the amplitudes and distance between the masses.

Table 1
(Assume $\omega^2 = 600$)

Item	I	$I\omega^2$	β	$I\omega^2\beta$	$\Sigma I\omega^2\beta$	k	$\frac{1}{k}\,\Sigma I\omega^2\beta$
1	4,000	$2.4(10)^6$	1.000	$2.40(10)^6$	$2.40(10)^6$	$800(10)^6$	0.003
2	4,000	$2.4(10)^6$	0.997	$2.39(10)^6$	$4.79(10)^6$	$800(10)^6$	0.006
3	4,000	$2.4(10)^6$	0.991	$2.38(10)^6$	$7.17(10)^6$	$800(10)^6$	0.009
4	4,000	$2.4(10)^6$	0.982	$2.36(10)^6$	$9.53(10)^6$	$800(10)^6$	0.012
5	80,000	$48.0(10)^6$	0.970	$46.56(10)^6$	$56.09(10)^6$	$20(10)^6$	2.804
6	51,000	$30.6(10)^6$	-1.834	$-56.12(10)^6$	$-0.03(10)^6$		. .

If the propeller of the example just given runs at 100 rpm and has three blades, the shafting will receive 3 × 100 or 300 impulses per min from it. As the diesel is a four-cycle engine, it will give the shaft 2 impulses per revolution or 200 impulses per min. The natural frequency of 234 cycles per min is about 28 percent below the number of propeller impulses, but only about 17 percent above the number of engine impulses. It would, therefore, be advisable to reduce the mass inertias or stiffen the shafts slightly to raise the natural frequency to about 250 cycles per min in this case.

If higher frequencies are assumed, it will be found that the torque summation may again be made equal to zero. These are the higher natural modes of vibration and are distinguished by the number of nodes, each mode having an equal number of nodes. They are of decreasing severity in amplitude but should be investigated to ensure safe operation.

Branch systems having high- and low-pressure turbines connected to a common propeller shaft through reduction gears are handled in a similar manner with the added condition that both branches must have the same amplitude at the bull gear (see Den Hartog, "Mechanical Vibrations," p. 236).

Lateral Vibration. In addition to the torsional vibrations just considered, lateral vibrations or critical speeds in which the shaft center line vibrates radially may occur in the shafting. If the operating and critical speeds are close together, a resonant condition will result. Then severe dynamic forces will be transmitted through the bearings to the hull, and the shafting system is subjected to strains. Hence it should be avoided.

The basic principles are covered on pp. 514 to 520 and so are not repeated here.

The shafting between the gears or driver and the stern-tube bearing is made so stiff from a stress standpoint that there is no danger of lateral-vibration trouble there. However, from the stern-tube bearing to the propeller, there may be considerable deflection and a possibility of vibration.

The procedure for determining the critical speed of this section follows that outlined on pp. 514 and 520. The shaft weight is approximated by a series of concentrated loads along its length, and the static deflection curve of shaft center line is calculated or approximated. It should be noted that for the lowest natural frequency the portions of the shaft in adjacent spans will deflect in opposite directions. Forward of the stern-tube bearing, the

Tooth Loadings:

$$\frac{F_t}{LD_p} = \frac{11{,}370}{20 \times 9.5} = 59.8 \quad \text{(less than 60, so satisfactory)}$$

$$\frac{F_t}{L\sqrt{D_p}} = \frac{11{,}370}{20 \times 3.083} = 184 \quad \text{(less than 190 to 225, so satisfactory)}$$

K Factor:

$$\text{Speed ratio} = \frac{440}{57} = 7.71 \cdot \frac{R}{(R+1)} = \frac{7.71}{8.71} = 0.885$$

$$K = \frac{F_t}{LD_pR/(R+1)} = \frac{11{,}370}{20 \times 9.5 \times 0.885} = 67.6 \quad \text{(within safe range)}$$

Endurance Strength of Teeth:

For pinion: Virtual number of teeth, $N_v = N/\cos^3\psi = 57/0.857^3 = 90.5$. $y = 0.255$ (from Table 1). $p_n = \pi/P_{dn} = \pi/7 = 0.449$ in.

$$\begin{aligned} s_t &= 225 \times 250 = 56{,}000 \text{ psi} \\ F_t &= 0.75 s_t p_n L y \cos\psi \\ &= 0.75 \times 56{,}000 \times 0.449 \times 20 \times 0.255 \times 0.857 = 82{,}900 \text{ lb} \end{aligned}$$

For gear: Virtual number of teeth, $N_v = N/\cos^3\psi = 440/0.857^3 = 699$. $y = 0.276$ (from Table 1).

$$\begin{aligned} s_t &= 175 \times 250 = 43{,}750 \text{ psi} \\ F_t &= 0.75 s_t p_n L y \cos\psi \\ &= 0.75 \times 43{,}750 \times 0.449 \times 20 \times 0.276 \times 0.857 = 69{,}800 \text{ lb} \end{aligned}$$

Dynamic Load on Teeth:

$$F_d = \frac{78 + \sqrt{V}}{78} F_t = \frac{78 + 111}{78} \times 11{,}370 = 27{,}550 \text{ lb}$$

Assuming an error in the profile of 0.0005 in., the corresponding value of C for stub teeth is $\frac{1}{2} \times 1720 = 860$.

$$\begin{aligned} F_d &= \frac{0.05V(F_t + LC\cos^2\psi)\cos\psi}{0.05V + (F_t + LC\cos^2\psi)^{1/2}} + F_t \\ &= \frac{0.05 \times 12{,}330(11{,}370 + 20 \times 860 \times 0.857^2)0.857}{0.05 \times 12{,}330 + (11{,}370 + 20 \times 860 \times 0.857^2)} + 11{,}370 \\ &= 16{,}430 + 11{,}370 = 27{,}800 \text{ lb} \end{aligned}$$

Limiting Wear Load on Teeth:

$$Q = \frac{2N_g}{N_g + N_p} = \frac{2 \times 440}{440 + 57} = 1.77 \cdot K = 79 \qquad \text{(from Table 2)}$$

$$F_w = \frac{D_pLKQ}{\cos^2\psi} = \frac{9.5 \times 20 \times 79 \times 1.77}{0.857^2} = 36{,}200 \text{ lb}$$

Since the strength and wear loads are both greater than the dynamic load on the teeth, the pair of gears will be satisfactory.

deflection may be assumed zero; *i.e.*, the end condition at the stern-tube bearing is "fixed."

The values of the concentrated weights, W_1, W_2, etc., and the corresponding deflections y_1, y_2, etc., are substituted in Eq. (32), p. 515, which is

$$N_c = 187.7\sqrt{\frac{W_1y_1 + W_2y_2 + W_3y_3 + \text{etc.}}{W_1y_1^2 + W_2y_2^2 + W_3y_3^2 + \text{etc.}}}$$

to determine the critical speed. All deflections are considered to be positive in this substitution; *i.e.*, the sign of the deflection is neglected. For safe operation, the critical speed should be 10 to 20 percent away from the operating speed.

Hull Vibration Due to Propeller. Owing to the pulsating torque previously mentioned, there will be a pulsating thrust on the propeller shaft. If this pulsating-thrust frequency approaches or coincides with the natural frequency of the hull, a hull vibration will be set up that may break the piping and cause general annoyance. If the natural frequency of the hull can be predetermined, this condition may be avoided. In general, attempts to stiffen up the hull when this condition arises have been unsuccessful. Changing the number of blades on the propeller seems to be the most practical solution. Sometimes it is necessary to have as many as five blades on the propeller.

DECK MACHINERY

BY

L. S. McCREADY

GENERAL

Deck machinery for merchant vessels as discussed here includes windlasses, cargo winches, mooring winches, capstans, and steering engines. It should receive the most careful attention from the designer because it plays a key role in the security, maneuverability, and earning capacity of the vessel throughout her career. One of the most fertile fields for development of original design is in cargo-handling machinery. Present methods are time-tried and well proven, but little in the way of new developments has come forward for years except the change from steam to electric power.

Upon the windlass falls the duty of handling the vessel's anchors with unfailing dependability. It is located in the most exposed part of the vessel and, like other deck machinery, generally receives a minimum amount of care. Its failure at an inopportune time may cause loss of the vessel or serious delay in her schedule.

The cargo winches play a key role in the over-all efficiency of the vessel in loading and discharging cargo. Any improvement in design and reliability will be reflected in substantial savings to the owners over a period of years, owing to the increased efficiency of cargo handling and shortening of the time in port.

Capstans and mooring winches play a less important role, yet they must be carefully designed and well made because, when they are in use, the vessel is in crowded waters being docked or undocked, and failure must not occur.

The steering engine plays a critical part in the operation of the vessel from the time her voyage begins until it terminates. Countless vessels have been lost or badly damaged from failure of the steering machinery. Wartime hazards from air and underwater attack place the highest premium on rapid and positive steering. Steering machinery must receive the most critical attention in its basic design. It cannot be overemphasized that it is of the highest importance in the over-all design and future operation of the vessel.

Many general requirements must be met in the design of all deck machinery. The basic design must conform to all the rules set forth by the U.S. Coast Guard, Bureau of Marine Inspection, and the American Bureau of Shipping. The latter body publishes annually its volume, entitled "Rules for the Classification and Construction of Steel Vessels." This volume, as well as all other pertinent rules, should be assiduously studied by the designer. Before starting design of deck machinery, its requirements must be established. Various factors to consider include the following, which should be given careful attention:

1. Reliability
2. Ruggedness and simplicity
3. Accessibility of all parts
4. Economy of operation
5. Quietness of operation
6. Lubrication and maintenance
7. Weatherproofing
8. Interchangeability of parts and motors with other machinery on board the ship
9. Adequacy of spare parts list
10. Ease of repair
11. Weight
12. Cost
13. National defense features
14. Guarding of moving parts
15. Protection from sabotage

MARINE REDUCTION GEARS

BY

AUSTIN H. CHURCH

REFERENCES: Buckingham, "Manual of Gear Design," Industrial Press. Waller and Peterson, Chap. 8, in "Marine Engineering," Soc. Nav. Arch. and Mar. Engrs. Gearing, pp. 816 to 829 of this handbook.

Since the operating speeds of modern steam-turbine or diesel drives are greater than the propeller speeds, it is necessary to employ reduction gears between the driver and the propeller line shaft. Marine reduction gears

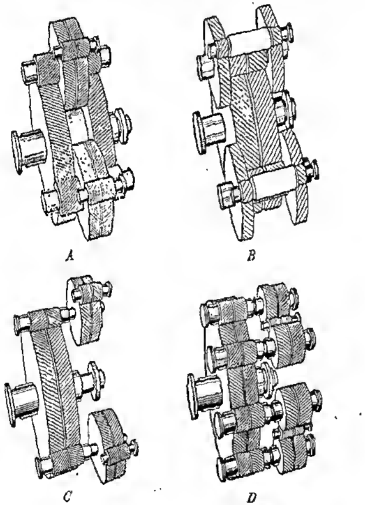

FIG. 1.—Typical marine double-reduction gear arrangements for use with cross-compound turbines. *A*, nested type; *B*, Victory ship nested type; *C*, three-case or articulated type; and *D*, lock-train type.

are always of the double-helix type. They are either single- or double-reduction, depending upon the speed ratio required. The maximum reduction ordinarily obtained with a single pair of gears is 10:1 or 12:1. When greater ratios are required a double-reduction train is used.

ANCHOR WINDLASS

Definition. A ship's windless is a power-operated device to hoist the anchors, drop them when desired, and to veer chain as required. It has a secondary function to handle lines and warps when the vessel is docking or undocking, which is done by means of drums or warping heads on extensions of one or more of its shafts.

Requirements. The windlass must be able to perform several operations:

1. Drop both anchors together or independently by using the brakes.
2. Slack out both anchors together by power.
3. Slackout either anchor by power, at will.
4. Veer chain on either anchor or both anchors.
5. Heave in both anchors together at not less than 30 ft per min.
6. Heave in either anchor at not less than 30 ft per min.
7. Warp hawsers with a maximum pull of 75 percent of hawser breaking strength.

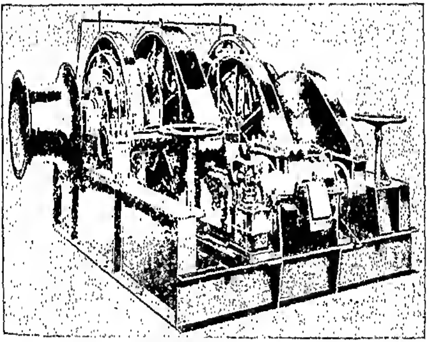

FIG. 1.—Anchor windlass.

Performance and Specifications. Specifications for the windlass are normally based upon the size of the vessel. The windlass on a typical cargo-carrying merchant vessel of 7,900 gross tons, displacing 17,000 tons, will have specifications similar to the following:

1. The windlass shall be capable of hoisting two bower anchors simultaneously from 30 fathoms of water at a chain speed of 30 ft per min. It shall be capable of hoisting one anchor and the maximum scope of 135 fathoms of chain under all service operating conditions.

2. Wildcats and warping heads shall be of cast steel. Their mountings shall not only safely withstand all service loads but also withstand stresses that may result in breaking a chain or snapping a hawser. Warping heads shall be of the smooth barrel type, without whelps.

ARRANGEMENT

There are three general methods of arranging double-reduction gears as illustrated in Fig. 1. The **nested type** shown in parts *A* and *B* is simple, compact, reliable, and has few bearings and couplings. The **articulated type** shown in part *C* has greater flexibility since quill shafts are generally used between the pairs of gears. The **lock-train** type of part *D* is more intricate but has greater load-carrying capacity, owing to the greater number of gears used. Since the points of contact of the first reduction pair are diametrically opposite, the lateral deflection of the pinion is eliminated.

MECHANICAL DETAILS

The gear casing may be cast of either iron or steel, or it may be built up of welded plates. The latter is lighter. One or more vents are provided to

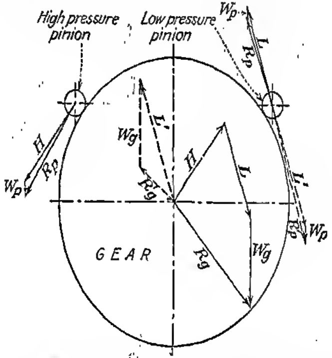

FIG. 2.—Graphical determination of bearing loads for second reduction gears driven by high- and low-pressure turbines.

remove the oil vapors from the casing. They should be located so that the vapors are removed from the engine room, *i.e.*, discharge into the exhaust ventilating system. The bearing supports should be very rigid to prevent misalignment under load.

The bearings are usually of the journal type, although on small sets roller bearings are sometimes used. The bearings are split perpendicularly to the load and usually supplied with oil under pressure. They are babbitt-lined in a cast-iron or steel shell. The bearing size is based upon a pressure of 100 to 200 psi of projected area, depending upon the rubbing speed of the journal. Since the gears and pinions have a double helix, the end thrust is balanced.

3. Each wildcat shall be fitted with a driving and locking head designed to lock in both engaged and disengaged positions. Each wildcat shall have a hand-operated brake of sufficient capacity to stop and hold the anchor and chain when "let go" under control of the brake. Chain clearers shall be furnished for each wildcat, fastened to the windlass bedplate.

4. Warping heads shall have a capacity of 29,000 lb each at 30 ft per min, and a light line speed 75 ft per min. The maximum line pull at the warping head shall not exceed 75 percent of the hawser strength estimated at 58,000 lb. The warping heads are to be driven on the main shaft ends.

5. The cast-steel common chain stoppers are to be furnished with the windlass. (The devil's claws are customarily furnished by the shipyard.)

6. The motor shall not be overloaded when hoisting one anchor. It shall not be overloaded more than 25 percent when hoisting both anchors.

7. The motor shall be at least 70 hp, compound-wound, 30 min rated after 1 hr at no load.

8. Electrical spares shall be furnished in accordance with rules of the American Bureau of Shipping, Sec. 35, Par. 72; U.S. Coast Guard, Merchant Marine Inspection Division; *Senate Report* 184, and the *A.I.E.E. Standard* 45, and the letter of the specifications.

General Design and Construction of Windlass. In windlass design, the most important considerations are

1. Reliability
2. Ruggedness and simplicity
3. Lubrication
4. Accessibility of parts
5. Weatherproofing of gears and electrical circuits
6. Ease of repair

The windlass is rather infrequently used and is in an out-of-the-way location. Hence, economy and quietness are of lesser importance. Considerable trouble will arise if the installation is not adequately weatherproofed. The windlass is in the most exposed part of the ship. In rough weather it is continually drenched by tons of breaking seas, sometimes for days on end. From subzero cold to tropical extremes, the equipment undergoes severe exposure. Inaccessible parts invariably rust after a few years' service. Out-of-the-way bearings may not receive adequate lubrication, and moisture tends to seep into the electrical circuits. The motor, brake, coil, and wiring are often on deck fully exposed and must have complete waterproofing. It cannot be overemphasized that the electrical installation must be exceptionally well weatherproofed. The bulk of all trouble developing in service arises from moisture accumulating in the controller, motor, or wiring.

The windlass is generally built up with commercial quality material from a cast-steel or fabricated welded-steel base and frame of heavy design. Machinery-steel shafting is employed, in common split, adjustable, babbitt-lined, or bronze bearings. The slow-speed shafts should have only bronze bearings. The main gear is best made of welded construction, with machine-cut teeth; pinions should be specified to be made from forged steel, and other gears may be of cast steel, all with cut teeth. All gears should be shrouded. The motor gear should be totally enclosed, running in oil. The gear housing should be fitted with a carefully designed vent to prevent climatic changes from causing condensation inside in cold weather, or expulsion of oil around the bearing in hot climates. The windlass bedplate should have an oil-retaining rim for cleanliness. The locking devices should be designed for

The transmitted force, F_t, acts tangentially to the pitch circles and equals 33,000 hp/V, where V is the pitch line speed in feet per minute and hp is the transmitted horsepower. The resultant load on the teeth acts along the pressure line and equals $F_t/\cos\phi$, where ϕ is the pressure angle.

The bearing loads are best determined graphically by adding vectorially the gear weight to the resultant tooth loads. The resultant of these forces gives the magnitude and direction of the bearing load. The bearings are split approximately perpendicular to these loads, and the bearing size is

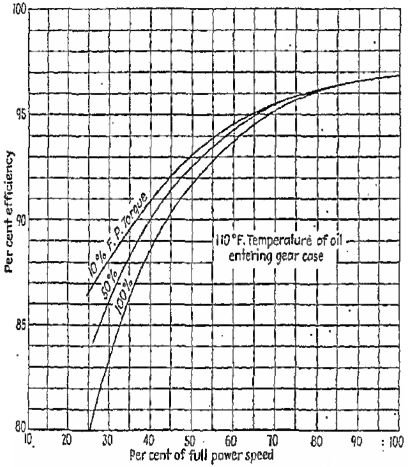

FIG. 3.—Typical efficiency curves of double reduction main propulsion gearing.

based upon their magnitude. Figure 2 illustrates the procedure. H and L are the resultant tooth loads of the high- and low-pressure pinions, respectively, W the gear or pinion weight, and R the resultant bearing load. The full lines represent ahead operation, while the dotted lines and primed letters apply to astern operation.

On large units, *high- and low-pressure turbines* operate in parallel, each having its own pinions as indicated in Fig. 1, and divide the load approximately equally for ahead operation. For astern operation, the low-pressure turbine supplies the entire power while the high-pressure pinion idles. A general rule for this condition is that the total power is 40 percent and the

extreme safety of operation, as this is normally a hazardous operation if there is any strain on the windlass.

Stresses in gearing, shafting, and other parts should not exceed 40 percent of the materials' elastic limit and maximum stresses should not exceed 80 percent of the yield point. On such materials as cast iron having no definite yield point, the working stresses should be calculated using a factor of safety of not less than 4. All forgings and steel castings should be of good commercial quality, stress-relieved. If heat-treated, the heat-treating should follow S.A.E. requirements.

When general design of the bedplate, framing, bearings, and parts of the windlass is undertaken, the proportioning is done in conformity with common machine-design practice and should present no difficulties. Welded structures are preferred to elaborate steel castings, and all parts should be robust. Although weight is not a factor to be neglected, strength and reliability are much more important and should in no wise be sacrificed to save weight. Parts should be designed for ease in disassembly. Standard tables of wrench clearances should be carefully followed in order that future maintenance work may be readily done, especially in cramped locations.

All windlasses have extensive gearing. Certain further details to follow in the design of gearing should specify gear bronze for worm wheels, and if larger than 8 in. in pitch diameter they should be made with a bronze rim on a steel center. Worms are made integrally with their shafts, heat-treated or case-hardened, depending on their size. Reduction-gear housings for worm drive should be made of welded steel or alloy cast iron, fully enclosed, and the worm shaft should have roller bearings to absorb annular and thrust loads. These gears run in oil, with suitable access plates and split joints in the housing for ready inspection and repair. Suitable plugs for filling, draining, and means for measurement of oil level must be embodied in the design. Pressure-gun lubrication fittings should be provided for all bearings not automatically oiled.

A suitable set of operating and lubrication instructions in the form of a framed chart should be provided in the specifications, to be mounted in the controller compartment, below deck.

The windlass motor is mounted on the bedplate, unless driving the windlass by an extension shaft from below decks. The coupling between the motor and reduction-gear train may be a flexible coupling of the all-metallic type.

Dimensions of windlass warping heads will vary roughly from 18 by 18 in. in a merchant ship of 10,500 tons D.W.T. to 24 by 24 in. in a vessel of 13,000 tons D.W.T. and upward. Designers should be careful that all warping heads on deck machinery are designed to be smooth, without whelps. Whelps damage rope severely when rope is surged over the head, and do not materially increase the frictional grip of the rope on the head. Although whelps damage the rope somewhat, they are effective, however, in gripping frozen mooring lines while smooth heads are not. Heads should be left unpainted. Vessels carry hawsers whose size is determined from the American Bureau of Standards rules, Table 16; they will be found to be approximately 8 to 8½ in. in circumference for the above vessels, for example. Table 1 gives the breaking strain of three-strand pure manila rope in pounds. The working strength is taken as one-fifth of the breaking strength. Four-strand rope has approximately the same tensile strength as three-strand rope. This table may be consulted in designing the required pull on windlass warping heads when rope size required on the vessel has been determined. Maximum designed pull should not exceed 75 percent of the breaking strength of the hawser.

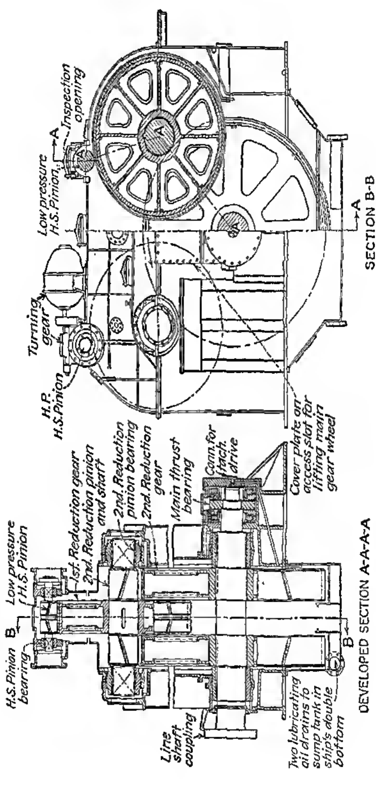

FIG. 4.—De Laval double-reduction gearing of the nested type.

Table 1. **Breaking Strength of Manila Rope**

Rope Circumference	Breaking Strain, Lb
5	22,500
5½	26,500
6	31,000
6½	36,000
7	41,000
7½	46,500
8	52,000
8½	58,000
9	64,000
9½	71,000
10	77,000
11	91,000
12	105,000

Further construction details specify cast steel for the wildcat locking head, bronze for the locking ring, and forged steel for the block keys. Brake linkage is actuated by a worm and wheel requiring not more than five turns of the handwheel from "full off" to "full on." The brake wheels have sockets in their rims for removable brake levers to use in locking and unlocking the brake bands.

Windlass motors are compounded with a heavy series field to give characteristics tending toward those of the series motor, which are ideal for hoisting service (see Fig. 2). The motor and controls are customarily designed to meet the specifications of the A.I.E.E., American Bureau of Shipping, U.S. Coast Guard, Merchant Marine Inspection Division, and *Senate Report* 184. Service on American cargo vessels is designed generally for 230 volts, direct current. Motors should be designed waterproof and provided with easy means of access for lubrication and servicing. Heavy-duty motors should have roller bearings, so designed that grease under pressure cannot be accidentally forced from the bearings into the motor housing.

Direct-current windlass motor control may well be designed so that the master-controller handle must be returned to the "off" position to reset the under-voltage relay, and the "off" position should be of sufficient width to ensure against inadvertently leaving the controller on either of the first positions. Control is the magnetic type, with combined dynamic lowering and reversing, designed to differentiate between warping duty and anchor-handling duty, with a step-back relay to limit the armature current under stalled conditions to 125 percent rated value and ensure satisfactory anchor handling and warping. The jamming or step-back relay is fitted in addition to regular overload protection. The windlass motor should have an electric brake on its shaft, like that on a cargo winch, of sufficient capacity to stop and hold the load under all service-operating conditions when hoisting or slacking out the anchors under power. All parts of the windlass should be assembled on the bedplate, except the resistors, control panel, and other control equipment located below deck.

Alternating current is being introduced rapidly in the merchant marine and Navy. Although winch duty is best served by d-c motors, windlasses may readily be designed for alternating current. In this case the general windlass design is followed as described, but the motor is a wound-rotor motor having high starting torque and low starting current.

speed 50 percent of that for ahead operation; hence the torque and forces acting on the low-pressure train are then 60 percent greater than for ahead operation, while the torque on the high-pressure train is zero.

The oil used for all the bearings and tooth lubrication is generally the same as that used for the turbines and usually has a viscosity of 400 to 600 SSU at 100 F. In addition to lubricating, the oil has the function of removing the heat generated. The hot oil is removed from the casing and passed through a heat exchanger. The cooling medium is sea water from the flushing line of the ship. After filtering, it is pumped to a gravity supply tank. The teeth are lubricated by spray nozzles located above and/or below the point of contact. Slow-speed gears are sometimes splash-lubricated by dipping into a reservoir of relatively high viscosity oil.

The **efficiency** of the unit is relatively high. The losses are due to friction between the teeth and in the bearings. Figure 3 gives typical efficiency curves for various torques and speeds and may be used for estimating purposes.

The **propeller thrust** is taken by the gear case through a thrust bearing of the Kingsbury or Michell type connected to the second reduction or "bull" gear (Fig. 4). This bearing must be able to absorb thrust in either direction for ahead and astern operation. The design pressure varies from about 250 to 400 psi.

The unit is provided with a **turning gear** (Fig. 4) attached to the high-speed pinion of the high-pressure turbine. This device is driven by a motor through a worm or reduction gear to cause the propeller shaft to make one revolution every 5 or 10 min for at least 2 hr without overheating. It is used to warm up the turbines, for inspection purposes, and to turn the gears over during long stays in port thus avoiding nonuniform corrosion of the teeth. There is also a provision for turning the gears by hand.

Flexible couplings are used to connect the turbines and pinions, and also between the first and second reduction gears in articulated trains. They are generally made with mating internal and external teeth. These teeth may be large and relatively few in number (9 to 16); or many small teeth may be used, giving a coupling of the Fast type. To secure satisfactory operation in absorbing the shock loads, oil films must be maintained between the contact surfaces.

The **pinions** are made of heat-treated forged carbon or nickel steel and generally have a Brinell number between 200 and 240. The **gears** may be made of cast iron or cast steel, the teeth being cut directly into the casting. For larger sizes the gear body may be made of cast iron or built up of welded steel plates, and a forged carbon-steel ring shrunk on the body. The Brinell number of the ring ranges from 160 to 200. The teeth are cut in the rim after the assembly of rim, body, and shaft is completed. The gear is then balanced.

The teeth are of involute form, generally of the 20-deg stub type, being hobbed and then run in with an abrasive or lapping compound. The normal diametral pitch ranges between 3 and 8, and the helix angle between 20 and 45 deg. The pressure angle in the plane of rotation ϕ differs from the normal pressure angle ϕ_n; the relationship between them being $\tan \phi_n = \tan \phi \cos \psi$, where ψ is the helix angle. The numbers of teeth in each pair of gears (and preferably in the entire train) should have no common factors that would tend to cause resonance and hence noise or vibration.

To secure an even load distribution across the face of the gears, their **deflection** must not be excessive. Since the gear is much heavier and

Power of Windlass Motor. The power of the windlass motor, of course, depends primarily upon the weight of both of the anchors and their chain. The weight of anchors required to be carried on the ship is determined from reference to the rules of the classification society, American Bureau of Shipping, or Lloyd's, depending on which rules were used in the building of the vessel. The American Bureau of Shipping rules, Sec. 24, state that the

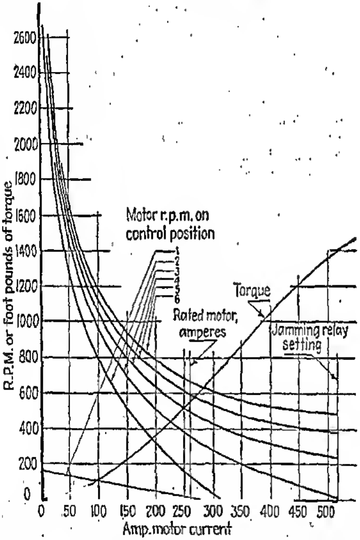

FIG. 2.—Anchor windlass motor characteristics—70 hp, 230 volts, direct current, 650 rpm. (*Courtesy of Westinghouse Electric & Manufacturing Company.*)

anchor weight is determined by the vessel's equipment tonnage. These rules further state that either ordinary or stockless anchors are permitted, but modern vessels all use the stockless pattern whose head is equal to not less than three-fifths of the total weight of the anchor. Table 16, American Bureau of Shipping rules, gives the required anchor weights and chain sizes, once the vessel's equipment tonnage is known.

Chains are led through the hawsepipes, whose friction is a more or less indeterminate factor. Practice has been to calculate the frictional efficiency

stiffer than the pinion, the usual assumption is that it does not deflect. The two kinds of deflection to be considered are the lateral and the torsional. The lateral deflection is usually limited by the empirical rules that the active face of the helices plus the gap (required to facilitate hobbing) between them or the total span divided by the pitch diameter of the pinion should not exceed 2.5 for a two-bearing pinion. The active face width of each helix divided by the pinion pitch diameter should not exceed 2 for three-bearing pinions. The torsional deflection is generally limited to 0.001 in., based upon the assumptions that the torque is removed at a constant rate across the pinion face and that the effective outside diameter of the pinion corresponds to the pitch diameter. The maximum torsional deflection in inches is given by $t = 0.013$ hp $D_pL/n(D_p^4 - d^4)$, where D_p is the pinion pitch diameter, d the inside diameter of a hollow pinion, L the width of active face in inches, n the rpm, and hp the transmitted horsepower. If the pinion is solid, this equation reduces to $t = 0.013$ hp L/nD_p^3.

TOOTH DESIGN

As it is essential that the gears give reliable operation for long periods, the tooth loads should be within safe values. Two empirical rules commonly used to determine these are $F_t/L = ADp$, where the symbols have the meanings given above, with the addition that A is a coefficient that is not greater than 95 for naval vessels, 50 to 60 for merchant ships, and about 40 for diesel drives. The second rule is $F_t/L = (190 \text{ to } 225)\sqrt{D_p}$, where the symbols have the meanings given above.

A more rational method based upon contact stresses involves a K factor as given in the equation $F_t/LD_p = KR/(R + 1)$, where R is the speed ratio (always greater than unity) and K is a factor dependent upon the service and reduction. It ranges from 65 to 110. On the Victory ships, K for the first reduction pair equals 100; for the second pair it equals 70.

A more detailed method of checking the design, based upon the strength and wearing ability of the teeth, is given in Sec. 3 of the "Manual of Gear Design" by Buckingham. The application to marine gears follows.

The load that can be transmitted for long periods of time without resulting in a fatigue failure, F_s, may be found by a modified form of the Lewis equation wherein the load is assumed to act approximately on the pitch circle, *i.e.*,

$$F_s = 0.75 s_t p_n L y \cos \psi$$

where s_t = bending endurance strength of the material and approximates 250 times the Brinell number

p_n = normal circular pitch, in.

L = active face width, in.

y = Lewis factor, taken from Table 1 and based upon the virtual number of teeth as found from $N_v = N/\cos^3 \psi$

N = actual number of teeth

ψ = helix angle

Owing to inaccuracies in the profile and spacing, the gears will suffer rapid accelerations and decelerations resulting in dynamic loads on the teeth which are frequently much greater than the load transmitted by the gears. There are two methods of calculating these dynamic loads. By the first method, $F_d = (3{,}000 + V)F_t/3{,}000$ for pitch line speeds (V) from 2,000 to 4,000 fpm; or $F_d = \left(\dfrac{78 + \sqrt{V}}{78}\right) F_t$ for pitch line speeds greater than 4,000 fpm.

of the hawsepipe at from 50 to 60 percent, the U.S. Maritime Commission not exceeding the latter figure. The over-all mechanical efficiency of the windlass itself should not be considered as being much in excess of 60 to 65 percent, although the gearing by itself is higher.

The main shaft, gearing, bearings, and other parts should be designed from a basis of transmitting maximum motor torque. Operating conditions in service are very rough indeed, however, indicating the need of generous proportioning of all parts and a factor of safety of not less than 4. Windlass hold-down bolts should have a factor of safety of 6. Knowing the weight of each anchor and 30 fathoms of chain and estimating the efficiency of the hawsepipe, windlass wildcats, gearing, and bearings, the motor horsepower can be calculated using the standard of hoisting speed of 30 fpm customarily used in all windlass design. The total weight to be hoisted is taken as that of both anchors and a total of 30 fathoms, or 180 ft of chain. Usually a generous addition to the calculated horsepower is specified to ensure ample power under adverse conditions, and actual hoisting speed may reach 40 fpm.

Spare Parts Specified. A specimen spare-parts list for the windlass installation is submitted below:

1 only	Armature
1 set	Coils, field, for motor
1 only	Coil, motor brake
1 set	Coils, contactor, one of each kind, for control panel
2 only	Assemblies, bearing, complete with inner and outer races and cage
2 only	Holders, brush, with 6 spare springs and stud insulation
2 sets	Brushes, motor
1 set	Grids, resistance, for control panel, comprising 1 grid of each size and kind
2 only	Elements, heater, for control and resistor enclosure heater
2 sets	Contacts, for controller, both fixed and moving, each size and kind
1 set	Springs, for controller contacts
1 set	Springs, brake
1 set	Linings, brake

ADDITIONAL INITIAL SUPPLIES AND TOOLS RECOMMENDED

1 only	Puller, gear, for motor brake wheel and motor and bell housing
1 only	Seater, brush
1 only	Undercutter, commutator
1 length	Wire, asbestos heatproof, for emergency-grid connections

The above list of spares is more complete than usual but will be found most worth while after the vessel is in service. A point to observe is to design the rack for any spare armature so that its shaft is vertical. If stored horizontally, a distortion of the coils may be expected to develop over a period of years.

Wiring. The windlass motor should be wired with varnished, cambric-insulated, leaded, basket-weave, bronze-armored cable, adequately protected where necessary and fitted with stuffing boxes of best design. An approved type of thermostatically controlled heater element should be provided in the enclosure for the motor and control panel to keep the equipment dry in damp weather, similar in design to heaters in winch-resistor houses.

Windlass Design on Oil-tank Vessels. Owing to the hazards natural to the carrying of volatile oil cargoes on these vessels, electrical deck machinery is not always used. On many such vessels the windlass will still be steam-driven. Its design will follow long-established practice and should present

Definition of A^B. Let $A = re^{i\varphi}$; then $A^B = \exp[(\log_e r + i\varphi)B]$.

For example, $i^i = e^{-\pi/2}$ where $i = \sqrt{-1}$.

If a is a positive real, $a^{x+iy} = a^x[\cos(y \log_e a) + i \sin(y \log_e a)]$.

Trigonometric and Hyperbolic Functions of a Complex Variable. If A is any point, then, by definition,

$$\sin A = \frac{e^{iA} - e^{-iA}}{2i}, \quad \cos A = \frac{e^{iA} + e^{-iA}}{2}, \quad \tan A = \frac{\sin A}{\cos A} \quad (\cos A \neq 0);$$

$$\sinh A = \frac{e^A - e^{-A}}{2}, \quad \cosh A = \frac{e^A + e^{-A}}{2}, \quad \tanh A = \frac{\sinh A}{\cosh A}.$$

Hence the formulæ that hold for these functions in the real case (p. 131; p. 135; p. 161) hold also for the complex case. Further:

$$\begin{array}{ll}
\sin(x + iy) = \sin x \cosh y + i \cos x \sinh y, & \sin iy = i \sinh y; \\
\cos(x + iy) = \cos x \cosh y - i \sin x \sinh y, & \cos iy = \cosh y; \\
\sinh(x + iy) = \sinh x \cos y + i \cosh x \sin y, & \sinh iy = i \sin y; \\
\cosh(x + iy) = \cosh x \cos y + i \sinh x \sin y, & \cosh iy = \cos y;
\end{array}$$

where $\sin x$, $\sinh x$, etc., are the ordinary trigonometric and hyperbolic functions of the real variables x and y. The functions $\sin A$ and $\cos A$ are periodic with a real period 2π. The functions $\sinh A$ and $\cosh A$ are periodic with a pure imaginary period $2\pi i$.

Logarithmic and Other Inverse Functions of a Complex Variable. If any point A is given, there will be an infinite number of points X such that $e^X = A$; any one of these points may be called a logarithm of A, and be denoted by $\log A$. All the values of the logarithm of A may be obtained from any one value by adding multiples of $2\pi i$.

If $x + iy = re^{i\varphi}$, then $\log_e(x + iy) = \log_e r + i\varphi \pm k \cdot 2\pi i$.

If any point A is given, there will be an infinite number of points X such that $\sin X = A$; any one of these may be denoted by $\sin^{-1} A$. The functions $\cos^{-1} A$, $\sinh^{-1} A$, etc., are defined in a similar way.

The elementary laws of operation which hold for these functions in the algebra of reals hold also, in a general way, in the algebra of complex quantities; but caution must be used, on account of the ambiguity in the symbols $\log A$, $\sin^{-1} A$, etc., which denote many-valued functions.

Differentiation of Functions of a Complex Variable. If $w = f(z)$, the derivative of w with respect to z is defined as

$$dw/dz = \lim \{[f(z + \Delta z) - f(z)]/\Delta z\} \text{ when } \Delta z \text{ approaches } 0.$$

It can be shown that $\lim \{[\exp \Delta z - 1]/\Delta z\} = 1$; hence $d(e^z) = e^z dz$, $d(\sin z) = \cos z \, dz$, etc., so that the formulæ for differentiation here are the same as in the case of a real variable (p. 157).

NOTE. For the algebra of vector analysis, which differs in important respects from the algebra of complex quantities, see p. 186.

TRIGONOMETRY

FORMAL TRIGONOMETRY

Angles, or Rotations. An **angle** is generated by the rotation of a ray, as Or, about a fixed point O in the plane. Every angle has an **initial line** (OA) from which the rotation started (Fig. 1), and a **terminal line** (OB) where it stopped; and the counterclockwise direction of rotation is taken as positive. Since the rotating ray may revolve as often as desired, angles of any magnitude, positive or negative, may be obtained. Two angles are **congruent** if they may be superposed so that their initial lines coincide and their terminal lines coincide. That is, two congruent angles are either equal or differ by some multiple of 360 deg. Two angles are **complementary** if their sum is 90 deg.; **supplementary** if their sum is 180 deg. (The acute angles of a right-angled triangle are complementary.) If the initial line is placed so that it runs horizontally to the right, as in Fig. 2, then the angle is said to be an angle in the 1st, 2nd, 3rd, or 4th **quadrant** according as the terminal line lies across the region marked I, II, III, or IV. The angles 0, 90, 180, 270 deg are called the quadrantal angles.

FIG. 1.

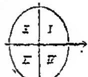

FIG. 2.

Units of Angular Measurement.

(1) SEXAGESIMAL MEASURE. (360 degrees = 1 revolution.) 1 degree = $1° = \frac{1}{90}$ of a right angle. The degree is usually divided into 60 equal parts called minutes (′), and each minute into 60 equal parts called seconds (″); while the second is subdivided decimally. But for many purposes it is more convenient to divide the degree itself into decimal parts, thus avoiding the use of minutes and seconds. (See tables, pp. 46–51.)

(2) CENTESIMAL MEASURE, used chiefly in France. (400 grades = 1 revolution.) 1 grade = $\frac{1}{100}$ of a right angle. The grade is always divided decimally, the following terms being sometimes used: 1 "centesimal minute" = $\frac{1}{100}$ of a grade; 1 "centesimal second" = $\frac{1}{100}$ of a centesimal minute. In reading Continental books it is important to notice carefully which system is employed.

(3) RADIAN, OR CIRCULAR, MEASURE. (π radians = 180 degrees.) 1 radian = the angle subtended by an arc whose length is equal to the length of the radius. The radian is constantly used in higher mathematics and in mechanics, and is always divided decimally. Table, pp. 44–45.

1 radian = $57°.30-$ = $57°.2957795131$ = $57°\,17'\,44''.806247$ = $180°/\pi$.

$1° = 0.01745\ldots$ radian = 0.01745 32925 radian.

$1' = 0.00029\,08882$ radian. $1'' = 0.00000\,48481$ radian.

(For 10-place conversion tables, see the Smithsonian Tables of Hyperbolic Functions, Washington, D. C.)

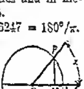

FIG. 3.

Definitions of the Trigonometric Functions. Let x be any angle whose initial line is OA and terminal line OP (see Fig. 3). Drop a perpendicular from P on OA or OA produced. In the right triangle OMP, the three sides are MP = "side opposite" O (positive if running upward); OM = "side adjacent" to O (positive if running to the right); OP = "hypothenuse" or "radius" (may always be taken as positive); and the six ratios between these sides are the principal trigonometric functions of the angle x; thus:

no unusual features. In certain tankers electric deck machinery will be used, but it must be given extremely careful design to eliminate danger from any inflammable vapors that could accumulate.

Weight Estimates. A rough estimate of windlass weight may be taken from Table 2, which is based upon the size of the stud-link anchor chain used on the vessel.

Table 2. Weight of Windlasses

Chain Size, In.	Weight, Tons
1	2.7
1¼	4.0
1½	6.0
1¾	7.0
2	9.0
2¼	12.5
2½	18.0
2¾	32.0
3	35.0

ELECTRIC CARGO WINCHES

Definition. A cargo winch is a power-driven cable-winding drum, horizontally mounted, whose shaft is extended to carry one or two winch heads or warping heads. Its principal purpose is to hoist or lower cargo, but it is frequently used for topping and lowering cargo booms, handling lines, and assisting in warping the ship in or out of her berth. Nearly all modern vessels are designed with electric cargo winches. Steam is still used on many new oil-tank vessels because of the reduced fire hazard. Winches are designed right- and left-hand, single- or double-geared.

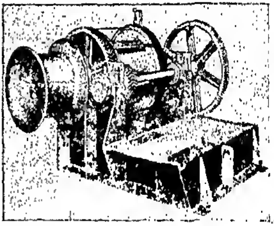

FIG. 3.—Cargo winch without motor. Note bedplate for motor.

Requirements. The cargo winch must be able to perform the following operations:

1. Pick up rated load without shock and accelerate to rated hoisting speed.
2. Decelerate the load being hoisted to a standstill without shock.
3. Lower the load under perfect control, and "lay it down" at approximately 10 percent of normal lowering speed when landing the load.
4. Stop lowering a load smoothly, without shock.
5. Stop a load automatically and smoothly in case of power failure.
6. Pick up a load from the deepest hold, hoist it, and lower it overside to water level when the ship is in light draft with one lay of hoisting wire left on the drum.
7. Have empty-hook speed double normal hoisting speed.

Performance. Drafts of general cargo up to 3 tons are handled on a single purchase or tackle by winches found in the merchant marine. Two tons on a

Layout. Depending on the size and kind of the vessel, particularly with reference to her stern design, the general layout is made. Larger vessels require two rams with four cylinders in all; smaller vessels employ one ram and two opposed cylinders. Rams actuate the tiller or rudder yoke in each case by the well-known Rapson slide, which has the advantage of transmitting an increasing torque as the rudder swings, provided a constant oil pressure is maintained in the cylinders. Other designs for large merchant or naval vessels use parallel links instead of a Rapson slide, as shown in Fig. 9. The controls for pumps and motors and the unit itself should be designed to

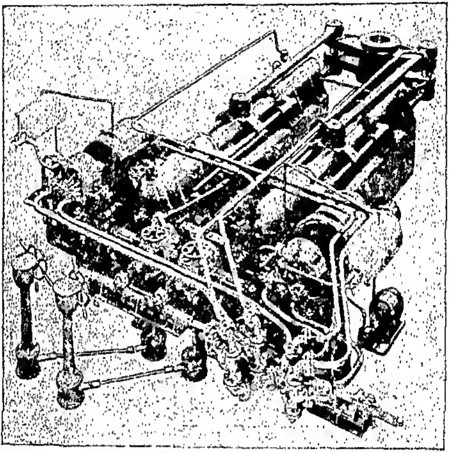

FIG. 9.—Electrohydraulic steering gear of parallel-link type as fitted to some C-3 cargo vessels. (*Courtesy of American Engineering Company.*)

minimize interference between working parts, particularly with reference to overhaul work which entails removal of various parts, both small and large. Clearance should be left for rise of the rudder stock when the vessel is laboring in heavy seas, and also for normal vertical weardown of the rudder as well as removal of the stock in shipyard when necessary. A ½ to ¾ in. allowance for weardown is common practice. A minor point not likely to be easily realized by the designer, for example, is the loss to the vessel if she cannot easily be kept on a steady, true course but must constantly be given an undue amount of corrective rudder. Such a vessel will consume noticeably more fuel, owing chiefly to the increased rudder drag but also to the increased work done by the steering engine and the longer distance sailed. A ship should be

single whip is the average maximum load hoisted at speeds from 200 to 300 ft per min; for medium-heavy lifts of 5 to 10 tons, a two-part purchase is used, with double-geared winches in low gear for the heavier loads. Heavy lifts

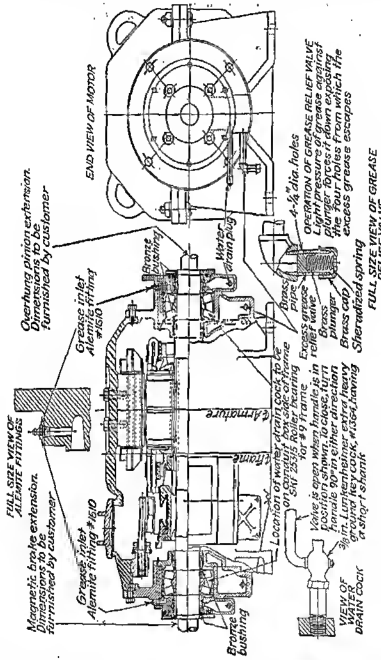

Fig. 4.—Typical winch motor. (Courtesy of General Electric Company.)

up to 30 tons, usually the limit on the ordinary cargo vessel's heavy-lift gear, are handled on a multiple purchase up to seven parts. Heavy-lift gear is served by compound-geared winches. Characteristic winch performance is presented in Table 3.

able to be steered by a good quartermaster so as to hold within $1\frac{1}{2}$ deg of her course in good weather, and not more than 3 deg in the average sea with force 3 wind.

Stresses and Loads. The loads imposed come from two sources: (1) the resistance offered by the water when the rudder is turned away from the centerline and (2) the motion of the ship in a seaway which tends to slam the rudder first one way and then the other, always with great force. The first can be calculated; the second is more or less indeterminate. The rudder is limited from turning more than 35 deg on each side, because to exceed this optimum angle gives no greater turning force but only increases the drag instead. In practice, the rudder seldom needs to move more than 10 or 15 deg from the centerline, except when maneuvering. When the vessel is sailing normally, the rudder torque seldom exceeds 10 percent of its maximum value, and the pump motors are accordingly but lightly loaded most of the time.

Torque on a rudder at positions up to approximately 15 deg will not greatly exceed 10 to 15 percent of the maximum hardover value at full speed ahead. Going astern, with 15 deg rudder angle, the torque is roughly between 30 and 40 percent full hardover astern value. The rudder, being of course greatly unbalanced in astern direction, causes greatly increased torque. Indeed, the limiting torque for design purposes is not always determined by the hardover torque at full speed ahead but, on the contrary, is determined by the hardover torque at full speed astern, which is greater, especially on twin-screw ships.

When running ahead, the steering engine is required to develop power to move the rudder to the right or left and overcome the water-pressure load on the rudder surface. The power required of the steering engine increases with the angularity of the rudder owing to the greater effective rudder area and the increase of distance of the center of pressure from the rudder stock. Thus the power for moving the rudder while the vessel is running ahead is greatest when the rudder is put hard over. The power needed by the steering engine decreases as the vessel responds to the rudder and starts to turn owing to the swinging of the ship and the increase in lateral pressure on that side of the rudder on the outside of the turning circle. The rudder torque, after the vessel responds to the rudder, is about 60 percent

Table 4

Rudder movement	Time, sec	Ram pressure	Motor, amp
Ahead maneuvering at full speed			
0-35L	13	1,000	26
35L-35R.	26	1,500	54
35R.-35L	23	1,050	36
35L-0	11	400	20
Astern maneuvering at full backing power			
0-35L	11	100	18
35L-35R.	22	450	24
35R.-35L	22	600	24

Table 3. Cargo Winch Performance

Hook load, tons	Line pull at drum, lb	Tackle	Nominal drum line speed, ft per min
No load	400	Single	525
1½	3,760	Single	290
3	7,400	Single	225
5	6,200	2 part	235
30	14,500	7 part	105

Winches on a somewhat smaller vessel of 10,500 gross tons handle loads up to 6,640 lb at the drum at 200 ft per min on a single whip, and 11,200 lb on the hook with a two-part purchase. This vessel carries a total of 10 such winches, 5 right-hand and 5 left-hand.

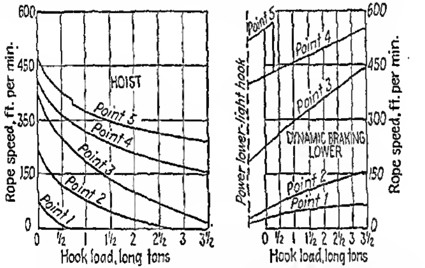

FIG. 6.—Characteristic curves of high-speed electric cargo winches. (*Courtesy of General Electric Company.*)

General Design. The essential characteristics to embody in the design of electric cargo winch installations are

1. Reliability
2. Smoothness of operation
3. Ruggedness and simplicity
4. Weatherproofing
5. Ease of lubrication and repair
6. Ventilation of resistor house or enclosure
7. Quietness
8. Adequate guarding of moving parts

Cargo winches are used intermittently. They remain idle for long periods during voyages, then are run under heavy duty while loading or discharging cargo. At sea, they are subjected to continuous and heavy drenching by salt water in tropical or freezing weather. The impact of heavy seas coming aboard strikes heavily upon the deck machinery, driving water into every part not waterproofed to the highest degree. In cold weather they are ice-coated, and dampness tends to set in in the winch resistor houses. When winches are in operation, they may likewise be running in freezing weather, which impairs their lubrication, or in extremes of tropical heat, which may

of the torque required to put the rudder hard over. It requires little or no power to return the rudder amidships when going ahead as the water pressure tends to do this. Table 4 shows how the steering engine of a large tanker was loaded during various trial-run maneuvers.

When running astern, any movement of the rudder away from the centerline is aided by the pressure of the water; in fact, the steering gear is then under negative torque and the steering engine actually retards the speed of movement. However, when putting the rudder amidships from its hardover position, it then requires the most torque when running astern.

For equal conditions of draft and speed it is obvious that the rudder torque when going astern is the greater, particularly where unbalanced rudders are used. The rudder may not be designed by the designer of the steering engine, but it is mentioned here that its type has a large part in determining the size of the steering engine required. Since balanced rudders will turn with much less power, the degree of balance and the pattern of the rudder will thus

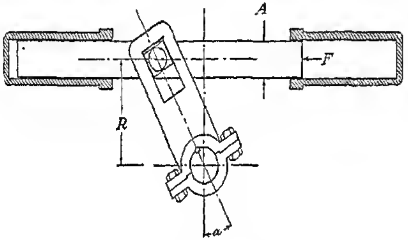

FIG. 10.—Ram arrangement.

influence the power required and hence directly influence the size of the steering engine itself.

The calculation of rudder torque from the hull and rudder dimensions is a very uncertain operation as most methods have been found to be unreliable—sometimes to the extent of 300 percent. Model tests furnish the only data on which any dependence can be placed and, for that reason, no formulas covering rudder torque are included here.

When the maximum rudder torque has been determined from model tests, the design can proceed.

A conservative figure for maximum shearing stress in the rudder stock is 5,000 psi. Commercial applications of machine steel for shafting will normally allow about 8,000 psi, but for the critical duty imposed on the rudder stock no greater than 4,500 to 5,000 psi should be allowed. The diameter of stock required can be calculated thus:

$$D = \sqrt[3]{\frac{16T}{\pi f_s}} \quad \text{or} \quad 1.72 \sqrt[3]{\frac{T}{f_s}}$$

overheat resistance grids and motors. They generally receive a minimum of care and maintenance and indeed are subjected to very severe duty.

Winch Motor Power. The power of winch motors is, of course, governed by the load to be lifted and the desired hoisting speed. In practice, however, cargo winches in the merchant service generally have 50-hp motors. Cargo lifts or drafts are measured in terms of long tons of 2,240 lb.

$$\text{Winch hp} = \frac{\text{line speed} \times \text{line pull}}{33{,}000 \times \text{winch efficiency}}$$

where line speed is in feet per minute and line pull in pounds. Winch efficiency is about 75 to 80 percent.

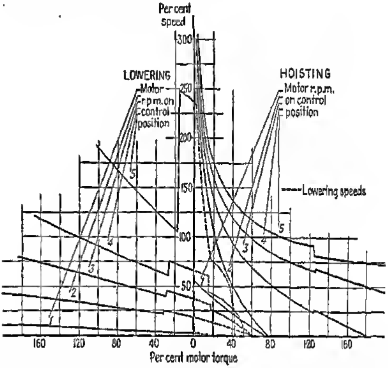

Fig. 6.—Cargo winch motor characteristics—50 hp, 230 volts, direct current, 600 rpm. (*Courtesy of Westinghouse Electric and Manufacturing Company.*)

The relationship between line pull and the load being hoisted depends upon the purchase of the tackle, for in multiple purchases much power is consumed in overcoming friction. The actual applied line pull at the winch is increased by an amount depending on the condition of the rope, the friction of the block, and the number of sheaves. A practical rule for calculating the actual pull required to hoist a load is to add 10 percent to the nominal load for every sheave over which the line passes; using this sum and the number of parts, calculate the power. This rule may be used safely in winch design.

Winch motors are customarily designed for 230 volts direct current, meeting the general requirements of the A.I.E.E. and U.S. Coast Guard, Merchant

where D = diameter of solid stock, in.
f_s = maximum allowable shearing stress
T = torque, lb-in.

The formula for determining the torque or moment the stock will withstand, becomes

$$T = \frac{\pi}{16} D^3 f_s$$

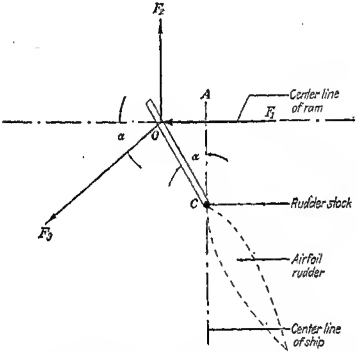

FIG. 11.—Force diagram of Rapson slide.

The working pressure in the rams can be chosen from the rated delivery pressure of the manufacturer's pump, usually 1,000 to 1,500 psi. Then the ram diameters can be calculated to give the desired torque at the rudder stock.

$$T = \frac{P \times A \times R \times E}{\cos^2 a} \qquad \text{(See Fig. 10)}$$

where T = torque on rudder stock, lb-in.
A = ram cross-sectional area, sq in.
R = normal tiller radius, in.
E = efficiency of ram, estimated at 80 percent
a = rudder angle
P = oil pressure acting on ram

NOTE: $\cos 35° = 0.819$; $\cos^2 35° = 0.671$.

Some steering installations have two rams. In such cases, of course, only half the force is produced by a single ram and the formula must be modified.

Marine Inspection Division. Winches run intermittently while handling cargo yet remain in general service many hours a day. Motors in this service heat to the same degree that they would if the winch were steadily operated at its fastest cargo cycle for 5 continuous hours. Winch motors should be of the waterproof, split-frame type, for locations on deck. Since winches nearly always operate gypsy heads as well, the motors should be compound-wound and rated at full load for ½ hr. They should have roller bearings, protected by spring-loaded relief valves from unintentional greasing to excess. Particular emphasis is laid upon accessibility of the motor and its sealing against the weather. Frequently trouble arises in service after the motor inspection plates are opened a few times because of failure of the gasketed joint to reseat absolutely waterproof.

Recent practice has been to build the entire winch and its control equipment in a single unit. The control panel, resistors, brake, and wiring are all enclosed, yet readily accessible. This arrangement saves deck space, eliminates deckhouses for winch controllers, and greatly simplifies the wiring necessary in the shipyard. Such winches on the average cargo ship have a 50-hp, 230-volt, d-c, compound motor turning 600 rpm and fitted with a vertical-type brake.

Control. Deck winches have magnetic, reversible control, very close acceleration and speed control, dynamic braking for lowering, and a magnetic brake on the motor shaft capable of controlling the load under any conditions. Small utility hoists below 15 hp may have manual control. The master controller and foot brake should be arranged for easy operation, but the master controller should not be located farther than approximately 24 in. from the hatch coaming. The effort for operating the motor brake is supplied by a helical spring which forces the shoes against the wheel when the magnet coil is deenergized. This coil is normally across the line and is rated for continuous service. When the brake is released, the pull rod pulls the shoes away from the wheel. Torque adjustments are made by changing spring compression by the spring support. The pull-rod assembly carries adjusting nuts to compensate for brake lining wear. All such fittings should be corrosion-resistant.

Construction. As in windlass design, normal stresses in gearing, shafting, etc., should not exceed 40 percent of the elastic limit of the material, and maximum stresses should not exceed 80 percent of the yield point. All parts of the winch should be strong enough to withstand stalling under maximum overload. Winches operate under severe duty, sustain shock loads, and must be ruggedly built. Material is commercial quality, following S.A.E. or A.S.T.M. specifications. The general requirements for winch gears, bearings, forgings, and castings may follow those given previously for windlass design. Winches may have spur gears, although most designers employ herringbone gears for greater smoothness and quietness. Single-geared winches have a gear ratio approximately 5:1. Compound-geared winches have a ratio of 10:1 or 15:1. The winches on passenger vessels in particular should receive most careful design to ensure quietness. Double-geared winches must have a positive steel jaw clutch, suitably enclosed. The gears must run in oil, in a casing properly vented and fitted with drain plug, filling plug, and oil-test plug for determining the oil level inside.

Winch drums vary from approximately 16 to 22 in. diam, from 18 to 30 in. in length, and are flanged. It is important to note in drum design that all the wire-rope hoisting cable must be able to be wound in not more than one

The Rapson slide has an interesting characteristic. The farther the rudder is put over, the greater the torque developed at the rudder stock by the mechanism of the slide (see Fig. 11). This figure shows the force diagram of a Rapson slide, and the abovementioned characteristic is explained as follows:

Case (*a*). Rudder amidships:

$$\text{Torque} = \text{ram force} \times \text{normal tiller radius}$$

or

$$= F_1 \times AC$$

Case (*b*). Rudder put over at angle a:

Torque = perpendicular force on tiller jaw × distance between rudder stock and force

or $= F_3 \times OC$

The relation between F_1 and F_3 and the torque is further shown thus, for any rudder angle a:

$$\text{Torque} = F_3 \times OC$$

$$F_3 = \frac{F_1}{\cos a}$$

As the rudder is put over, the effective tiller arm increases thus:

$$OC = \frac{AC}{\cos a}$$

Hence,

$$\text{Torque} = \frac{F_1}{\cos a} \times \frac{AC}{\cos a} = \frac{F_1 AC}{\cos^2 a}$$

The net effect of the increased effective tiller arm and multiplication of the force applied by the ram is an increase in rudder torque governed in amount by the square of the cosine of the rudder angle. Those steering gears employing two rams and four cylinders simply divide the total torque between two rams. The basic design, of course, remains the same.

The stroke of the ram will be sufficient to turn the rudder slightly more than 35 deg. Designers specify from 36 to 40 deg as the maximum possible movement of the tiller before the rams meet mechanical interference.

$$\text{Stroke of ram} = R \tan a$$

where stroke = in.
R = normal tiller radius
a = rudder angle from the centerline

Total stroke, from hardover to hardover, is twice this value.

To calculate the ram horsepower, it is necessary to know the maximum load and the number of seconds desired for the ram to make the stroke from

"lay" or layer on the drum. The only exception to this is the winch used for the heavy-lift gear where not more than five lays should be wound upon the drum. Drums should have a suitable clip for securing the cable, which is led through a 1-in. hole or slot at the end of the drum, either radially through the drum at the flange or else tangentially through the flange itself. They should have well-designed wire-rope guards to prevent accident to winchmen or fouling of the cable. The drum must have sufficient wire capacity to lower the hook to the bottom of the vessel's cargo hold and still have one complete turn holding on the drum. Drums should have a strong foot brake of sufficient capacity to stop and hold the loads under all conditions of operation. Winch heads for warping duty should be made of cast steel or alloy cast iron, without the projections or whelps formerly used for greater friction, and be made of a grade of material with maximum properties for resisting the abrasion incidental to long service. Drums should be made of cast steel or good-grade alloy cast iron. Bearings on the drum shaft are usually bronze-bushed. Drums are not grooved for the rope but are left smooth. The design of the winch must ensure that its acceleration and braking will not be great enough to overstrain the cable or any parts. Wire rope used on cargo winches varies generally from ½ to ¾ in. in diameter. It is nearly always specified as ungalvanized, six-strand, 19-wire improved plow-steel wire rope. The designer's factor of safety should be 5.

Winch Spares. Ample spares for the winches should be specified. Cargo ships carry from 10 to 20 winches of similar design, all working on a strenuous schedule. Winch breakdowns occur when the winches are working cargo at a time when they can least afford to be out of service. Breakdowns may occur in remote parts far from any source of extra parts. Such occurrences cause serious delay in cargo handling and entail attendant confusion and loss of earning power for the vessel. Specifications of the vessel's design should call for enough spares for the winches to be adequately serviced. Spare-parts lists should be specified from consultation with rules of the same societies previously listed under windlass design. A specimen list is submitted below. The designer may find that the owner prefers fewer spares to be included in the original contract for the vessel, desiring instead to put more spares aboard after delivery of the vessel.

1 only	Armature, for each six motors of same size
1 set	Coils, field, for each six motors of same size
1 only	Coil, motor brake, for each six motors of same size
1 set	Assemblies, bearing, complete, for each six motors of same size
1 only	Holder, brush, for each six motors of same size
1 set	Brushes, motor, for each three motors
1 set	Grids, resistance, for control panel comprising 1 grid of each size and kind for each six controllers
1 only	Element, heater, for control and resistor enclosure heater
2 sets	Contacts, for controller, both fixed and moving, for each four controllers of same design
1 set	Springs, for controller contacts, for each four controllers
1 set	Springs, brake, for each four winches
1 set	Linings, brake, for each four winches; with spare shoes for each eight winches
2 only	Fuses, for each fuse installed up to maximum of 30 spares, for each rating. Renewable links, where used, should include five renewals for each fuse and 10 percent of each size of fuse case

Further additions or deletions to the above list may be made according to owner's desires, manufacturer's recommendations, special trade-route

hardover to hardover. A minimum of 30 sec for this is allowable, and the ram should actually be able to accomplish this stroke in somewhat less time.

$$\text{Hp} = \frac{A \times P \times D}{550 \times t \times E}$$

where A = cross-sectional area of ram, sq in.
P = working pressure, psi
D = distance moved by ram, ft
t = time, sec
E = efficiency of ram, estimated at 80 percent

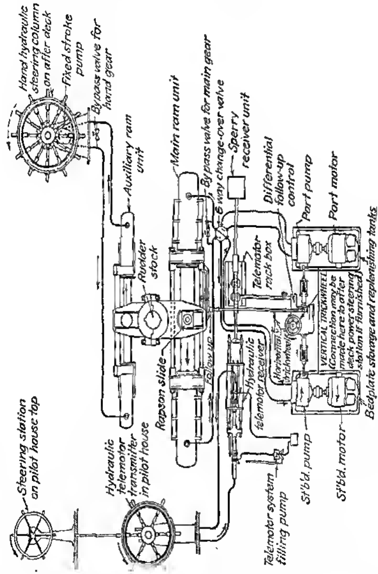

FIG. 12.—Typical arrangement of electrohydraulic steering gear. (Courtesy of American Engineering Company.)

To determine the power of the motor required, an increase is necessary to allow for the normal loss in pump efficiency. The oil pumps used on electrohydraulic systems have approximately 85 percent efficiency.

requirements, and changes in the requirements of the classification societies.

Wiring. Winches should be wired with varnished, cambric-insulated, leaded, basket-weave, bronze-armored cable, well protected by kick pipes, thimbles, and stuffing boxes on deck, and mechanical protective guards as necessary. As specified for the windlass controller, the winch houses for the controller should be provided with thermostatically controlled electric heaters to keep the panels, coils, and contacts dry in damp weather. A further source of trouble is the extreme heat reached in these enclosures when cargo is handled in the tropics. The overheating or "sagging" of resistance grids is not at all uncommon, and the ship's electrician must make repairs by jumping the grid or fitting a spare one under adverse conditions. The house should have an electric blower of from 800 to 1000 cfm capacity, or sufficient to create an air change at least once a minute in the compartment.

Practice may specify mounting several control panels in the house together, or on a common panel. Winches of unit-type design have all necessary controller parts and wiring inside their own individual casings. Exceptional provisions for waterproofing should be made in the entire installation in any event.

Weight of Cargo Winches. Electric cargo winches may vary in weight from approximately 5,800 to 10,000 lb. For general examples, an open-type, 50-hp, compound-geared, two-speed winch will weigh about 9,000 lb. One design of heavy-duty, electric, two-speed, single-drum winch used for handling extra-heavy deck loads, such as locomotives, weighs 12,000 lb.

MOORING WINCHES AND CAPSTANS

Mooring Winches

Definition. Mooring winches, sometimes called **warping winches**, are essentially cargo winches with no drum and long extensions on the main

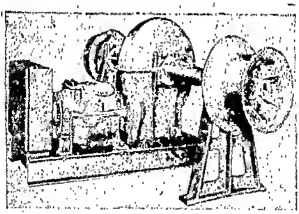

FIG. 7.—Mooring winch

shaft which carry warping heads. Also fitted near the ends of the shaft, inboard of the pedestal bearings, are smaller grooved drums for winding wire rope.

The purpose of the warping winch is primarily for warping the ship during docking and undocking. It is also occasionally used for hoisting boats and handling cargo booms. The winch is usually located well aft, so that its

$$\text{Motor hp} = \frac{\text{ram hp}}{\text{efficiency of pump}} = \frac{\text{ram hp}}{0.85}$$

Emergency Provisions. Each motor must be capable of operating the rudder when the ship is going ahead at maximum shp and full-load draft, or astern at full astern power and full-load draft. The motor should not be overloaded more than 25 percent during any maneuvering astern. The design of the selector valve should enable both pumps to be run at once when desired, since when the vessel is maneuvering this enables the rudder to be swung much more rapidly and contributes much to the maneuverability

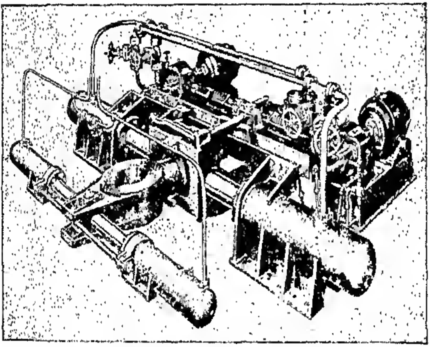

Fig. 13.—Electrohydraulic steering gear on the tanker, "Pennsylvania Sun." (*Courtesy of American Engineering Company.*)

of the ship. Those installations having duplex rams need have no separate relieving tackle or separate auxiliary gear, and one ram alone should be able to handle the rudder up to half the ship's designed full-ahead speed. In case the system becomes inoperative, there should be a hand-operated rudder brake strong enough to hold the rudder in position. On many occasions the rams will put the rudder hard over and the "hardover stops" for limiting the ram movement should be able to withstand the full load on them. These stops will be set at 35 deg but will allow overtravel to a 37- or 38-deg positive stop location. Some designers make them adjustable. Usual design limits the maximum working oil pressure during ahead or astern maneuvering to 1,500 psi. The separate oil-storage and drain tank should have a capacity at least 120 to 130 percent of the system's capacity. It is provided with its own pump and piping. The unit should have a trick wheel for each pump and control unit directly connected to its control differential.

wire-rope drums can be used for emergency steering. As the shaft turns, one drum winds the steering-gear emergency relieving tackle while the other drum unwinds on the other side. Control of the winch will thus steer the ship by power when other means fail if the steering gear is designed to permit this. A warping winch is generally preferred to a capstan if there is sufficient room. Its shaft lies in an athwartship direction.

Design. A warping winch should have a light line speed of from 75 to 90 fpm, for taking in slack lines. The pull may be taken at not over 2,500 lb under this condition. When warping, the winch should develop a pull on the lines equal to at least half the breaking strength of the hawsers and warps required to be carried on the vessel. It should be able to withstand full breaking strength of this line, without damage. Working pull is about one-third the breaking strength of the line.

The warping winch may be single- or double-geared. In general, its design follows requirements already discussed under windlasses and winches. Its outboard shaft pedestal bearings, of the sleeve type, must withstand the full pull of a breaking hawser. Warping heads are smooth. No brakes need be fitted. The control must be reversible, and its design is more or less similar to cargo winch design.

Its power may be calculated on the basis of the required warping line speed and the rated pull. The winch efficiency is about 70 to 75 percent.

$$\text{hp} = \frac{\text{line speed} \times \text{line pull}}{33{,}000 \times \text{efficiency}}$$

Capstans

Definition. A capstan is a motor-operated vertical drum used principally for warping the ship while docking or undocking. In warping ship, a line is sent ashore and made fast at the dock or pier. The capstan is then used to put sufficient strain on the line to draw the ship slowly toward the dock.

Design. A capstan must be well and carefully designed. In service, it is subjected to heavy loads created by the movement or inertia of the entire vessel. Its chief requirements are that it must accomplish the following:

1. Run in either direction.
2. Have provision for hand operation in event of power failure.
3. Have a light line speed from 70 to 80 fpm.
4. Have a loaded line speed of approximately 30 fpm.
5. Have a motor brake sufficient to control full load.
6. Develop rated pull equal to 75 percent of the breaking strength of the hawsers specified for the vessel.

Requirements. Capstan design is based upon the key requirements of reliability, ruggedness, and weatherproofing. Economy, quietness, weight, etc., are of much less importance. The capstan is not run for long periods at a time, being altogether different in this respect from cargo winches. In general, the proportioning of parts and the selection of material follow the previously discussed material given under windlass design.

Capstan power is determined from the rated line pull and rated line speed under load, in the same manner as the calculations given for determining the power of mooring winches. Motors and controls follow windlass and winch design rather closely, with the exception that a-c wound-rotor motors

Materials and Construction. The bedplate must be very strong and rigid for transmitting the heavy forces safely to the ship's framing. Generally this is of welded-steel construction. The cylinders are of cast steel fitted with bronze guide bushings and oil-resistant outside packing for the rams. The rams may be solid, hollow-forged steel with a plugged end or built up from welded steel and machined. Long service causes the packing to wear a neck in the rams at the point of their most frequent travel, when the rudder is more or less amidships. To avoid this, the ram surface in that location should be casehardened or flame-hardened before the final finish is ground. The crosshead or tiller should be of cast steel, heavily keyed to the stock. Guide blocks, guide rods, tie rods, pins, and other stressed parts should be of forged steel. All parts of the storage motion control should be

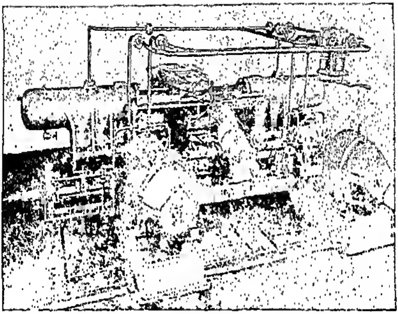

FIG. 14.—Steering gear of type fitted to some C-2 cargo vessels. (*Courtesy of American Engineering Company.*)

casehardened or heat-treated to resist wear. All heavy parts should be provided with one or more bosses tapped for oversize eyebolts for lifting during overhaul. Heavy bearings should be provided with wick-feed or automatic lubricators.

Piping. The piping in the high-pressure system must be of seamless steel, with bolted flanged joints, tested at maximum relief valve pressure of the system. The relief is set about 15 percent above working pressure. Screwed, or screwed and welded, joints are not allowed. Relief valves and vent cocks are fitted as required. High-pressure piping should be sized to permit velocity of oil flow not in excess of 18 or 20 fps. Low-pressure tubing should be of annealed copper with coned joints. Brazed joints should be avoided as they tend to produce foreign matter in the form of bits of spelter or flux, which get in the system. The oil-supply tank should be located not less than 3 or 4 ft above the highest part of the piping. All oil-tank-filling

may be used for capstans though they would not be desirable in winch work owing to the marked superiority of direct current for the latter service.

The capstan is built up from a substantial cast-steel or welded-steel base provided with exceptionally rugged means of being secured to the deck. The drum is of cast steel or alloy cast iron, smooth-barreled and driven by an extension shaft through the weather deck from the worm wheel inside the base. The worm is sometimes driven by a spur gear reduction from the motor; otherwise by direct coupling to the motor shaft. If both spur and worm gearing are embodied in the design, separate oil enclosures should be provided in a common, rigid housing because they require different grades of oil. The worm is carried on ball bearings designed for both thrust and annular loads.

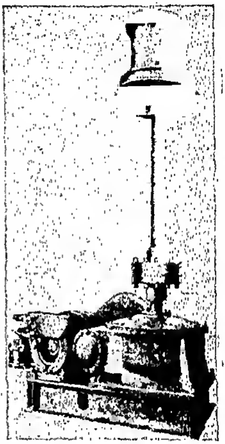

FIG. 8.—Capstan with extension shaft so that the drive may be mounted below the weather deck.

Proportioning of shafting and gearing is done on a basis of transmitting maximum motor torque and, further, resisting safely the strain brought by a breaking hawser. Capstan drive must be self-overhauling and, since worm drive is employed, the hawser's pull on the drum cannot overhaul or turn the motor under this condition unless the helix angle of worm and wheel is at least 15 deg. The vertical capstan shaft is of two-piece design and arranged with a slip joint to provide adequate lift and allow for ½ to ¾ in. deflection of the deck above the motor when the unit is working under heavy strain.

The motor, usually 230 volts, compound-wound, is 30 min rated after 1 hr at no load. It is the heavy-duty marine type, with roller bearings. Its maximum speed should not be exceeded if load is thrown off the capstan. Motor control is usually the magnetic reversing type, with a torque limiting relay positively limiting line pull on the drum of 75 percent of the warping hawser's breaking strength. No overload relay is required. In general, the motor and control equipment should provide 5-point control, automatic acceleration, adequate torque to maintain specified line pulls, and protection against stalling and low voltage.

STEERING MACHINERY

Introduction. The importance of the steering machinery has been previously mentioned. This discussion leaves out entirely all mention of various mechanical hand gears, drum and cable-controlled tillers, or small chain- or screw-type gears fitted on small ships. The only kinds of steering

openings should be designed for locking to prevent sabotage from emery or carborundum dust being thrown in the oil. The entire steering engine room should, in fact, be kept locked, if sabotage is thought possible.

Motor Selection. On hydraulic systems the commonly used motor is 230 volts, shunt-wound, dripproof, constant-speed, 1 hr rated, fitted with ball bearings. On direct-drive systems the motor is compound-wound. The duty imposed offers no problem in control and the common across-the-line starter is used. Motor-starting push buttons should be located near the trick wheels and the six-way valve controls, to minimize the time necessary for emergency changeover. The A.I.E.E. requires a spare set of bearings, a brush holder, and a set of brushes to be carried as spares for each motor.

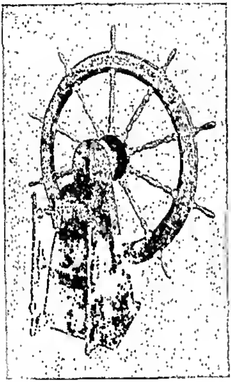

FIG. 15.—Hydraulic telemotor steering stand. (*Courtesy of American Engineering Company.*)

The designer or owner may desire more, however. 440-volt, three-phase, 60-cycle alternating current is gaining rapidly on merchant and naval vessels and a-c steering engine motors are well adapted to this service. Motors have overload relays, and a-c installations should have alarm lamps indicating open phases or reversed phase sequence.

The undervoltage release for each steering motor is located in the steering engine room and should provide automatic restarting upon restoration of the ship's voltage. Motor feeders should run to each motor from two separate cables, with transfer switches, from the main switchboard, one being on each side of the ship. The overload protection should be located on the ship's main switchboard, provided with audio and visual signals to tell when either motor loses its current supply. Each motor requires an indicator light

machinery considered suitable for oceangoing vessels are direct-drive electric gear and the more popular electrohydraulic ram-type gear. Steam steering machinery is considered obsolete in so far as progressive new design is concerned.

The electrohydraulic gear is by far the most efficient. Unlike the direct motor drive, its motor need not be stopped and reversed to reverse the rudder but may run continuously at all times, its load being varied according to the telemotor control. Its characteristics permit low headroom, relatively light weight, and many various methods of locating the rams, pumps, and controls to suit the vessel's design.

Societies governing design of steering machinery are the American Bureau of Shipping, U.S. Coast Guard, Merchant Marine Inspection Division, A.I.E.E., and also *Senate Report* 184. To these must be added the owner's special requirements and, of course, any and all special national defense features required to be embodied in the design by the Navy. The scope of steering machinery in this discussion extends from the calculation of rudder torque from the rudder shape and area as determined by the naval architect, through the entire design of the steering machinery itself, the elements of telemotor design, and in general all detail work necessary to design the installation including the steering stand and telemotor control.

Basic Requirements. Steering machinery should be designed to carry out the following functions on any oceangoing vessel over 250 ft long:

1. Move the rudder smoothly to any desired position within limits of 35 deg left or 35 deg right of the ship's centerline.
2. Move rudder from hardover to hardover through a total of 70 deg in not more than 30 sec when vessel is going ahead at a speed corresponding to maximum shp at full-load draft.
3. Move rudder from hardover to hardover through a total of 70 deg in not more than 60 sec when the ship is going astern, at a speed corresponding to maximum astern hp at full-load draft.
4. Move rudder by means of an emergency source of power from 15 deg left to 15 deg right through a total of 30 deg in not more than 60 sec when the vessel is going ahead at half the maximum designed sea speed or 7 knots, whichever is greater.
5. Have a brake on the rudder stock, or have a hand oil pump on the rams capable of producing a torque equal to one-fourth the maximum ahead torque.
6. Hold the rudder in any desired position against all stresses imposed upon the rudder during normal operation of the ship.
7. Yield under influence of extreme stresses imposed upon the rudder in heavy seas, and return automatically to the set position when the overload has passed.
8. Operate with 100 percent reliability by designing with main, auxiliary or stand-by, and emergency power.
9. Operate quietly, accurately, and economically.

General Qualifications. The steering machinery should be designed from the general consideration of the following essential characteristics:

1. Reliability
2. Strength
3. Economy
4. Accessibility of parts
5. Quietness of operation
6. Ease of maintenance and repair
7. Ease of changeover to emergency gear
8. Positiveness of telemotor control
9. Protection from sabotage

in the engine room. Audio alarms have a silencing and reset button in the engine room to be used after the alarm is noted by those on watch.

Pump Selection. The Hele-Shaw and the Waterbury pumps are most frequently used. These are the popular radial piston or axial piston designs, much used for hydraulic-pressure service. They stand up excellently under long operation, and no excess capacity need be allowed for them in design of the steering machinery as they maintain nearly constant efficiency throughout their life. They should be selected at a rating equal to 90 percent of their full stroke capacity. A flexible coupling should be provided between the motor and the pump. Those pumps of parallel-piston design need adequate provisions for recirculating the oil. Radial pumps need a motor-driven leak-off pump and tank for each pump to return the maximum possible amount of leakage oil to the replenishing tank. A 10-gal capacity will suffice for the overhead replenishing tanks. The oil for the system is a high-grade mineral oil, like turbine oil, of "heavy-medium" viscosity, although sometimes an "extra-heavy" oil may be used.

Telemotor Control. The telemotor is the control whereby the helmsman at the wheel transmits mechanical motion to the steering engine itself to set the power mechanism of the latter in operation. Formerly wire or steel shafting was used, running directly from the wheelhouse, but this is now obsolete. Only the hydraulic telemotor and the electrical control are now used. Figure 15 shows a hydraulic telemotor steering stand. Telemotors use medium-grade pure mineral oil. Of course glycerin and water can be used, but oil is preferred. The oil should have a cold pour point 40 deg below 0 F. All large modern vessels have a Sperry gyro-control unit for automatic steering, which also actuates the steering engine control when so desired. The telemotor and the Sperry unit both control the stroking of the oil pumps, hence the steering itself. All steering machinery should have suitable follow-up gear. Ships generally may be steered from three locations: pilot house, aft steering station, and steering-gear room. Some may be steered from the top wheelhouse if so constructed.

Requirements of telemotor design are

1. Reliability
2. Simplicity
3. Tightness of connections
4. Protection from loss of control by freezing
5. Absence of excessive number of connections between wheel and steering engine
6. Freedom from disturbing magnetic influences near compasses
7. Automatic equalizing when wheel is amidships

Hydraulic Telemotors. These follow conventional design throughout. Telemotor tubing requires care in installation, however. It is copper tubing, ½ to ¾ in. in diameter, led as straight as possible. It should always lead forward on a constantly rising level, avoiding all dips and excessive bends. Care should be taken to keep it clear of boiler tops, the fiddley, steam lines, etc. It should be designed for a 500-lb test pressure, although working pressure is much lower. The charging tank will generally be 7 or 8 gal; the forward replenishing tanks hold about 3 gal as part of the telemotor housing. Air cocks should be provided for venting.

Electric Telemotors. Those vessels having alternating current for auxiliary use, as well as main propulsion, are suited for a "synchro-tie" or

$$\begin{aligned}
\text{sine of } x &= \sin x = \text{opp/hyp} = MP/OP;\\
\text{cosine of } x &= \cos x = \text{adj/hyp} = OM/OP;\\
\text{tangent of } x &= \tan x = \text{opp/adj} = MP/OM;\\
\text{cotangent of } x &= \cot x = \text{adj/opp} = OM/MP;\\
\text{secant of } x &= \sec x = \text{hyp/adj} = OP/OM;\\
\text{cosecant of } x &= \csc x = \text{hyp/opp} = OP/MP.
\end{aligned}$$

The last three are best remembered as the reciprocals of the first three:

$$\cot x = 1/\tan x;\ \sec x = 1/\cos x;\ \csc x = 1/\sin x.$$

Other functions in use are the versed sine, the coversed sine, and the exterior secant:

$$\text{vers } x = 1 - \cos x;\ \text{covers } x = 1 - \sin x;\ \text{exsec } x = \sec x - 1.$$

For graphs, see p. 174; series, p. 161.

Signs of the Trigonometric Functions

If x is in quadrant	I	II	III	IV
$\sin x$ and $\csc x$ are..................	+	+	−	−
$\cos x$ and $\sec x$ are..................	+	−	−	+
$\tan x$ and $\cot x$ are..................	+	−	+	−

vers x and covers x are always positive.

Variations in the Functions as x Varies from 0 to 360 deg are shown in the accompanying table. The variations in the sine and cosine are best remembered by noting the changes in the lines MP and OM (Fig. 4) in the "unit circle" (that is, a circle with radius $= OP = 1$), as P moves around the circumference.

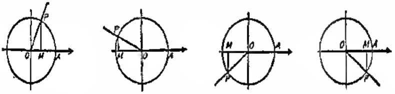

FIG. 4.

$\sqrt{2} = 1.4142$; ½$\sqrt{2} = 0.7071$; $\sqrt{3} = 1.7321$; ½$\sqrt{3} = 0.8660$; ⅓$\sqrt{3} = 0.5774$; ⅔$\sqrt{3} = 1.1547$

Trigonometrical Tables. The tables on pp. 46–56 give the values of the principal trigonometric functions and of their logarithms, correct to four places of decimals, the angle advancing either by tenths of a degree (p. 46) or by 10 min (p. 52). These tables will be found adequate for most

computations in which an accuracy of 1 part in 1000 is sufficient. If much computing is to be done, it is advisable to use a separate volume of tables, containing more facilities for interpolation, and printed in larger type, such as the four-place tables of E. V. Huntington (Houghton Mifflin Company, Boston, Mass.), with convenient marginal tabs; the five-place tables published by Macmillan or many others; the six-place tables of Bremiker; the standard seven-place tables of Schrön, Vega, or Bruhns (angles advancing by 10 sec); or the great eight-place of Bauschinger and Peters (angles advancing at intervals of 1 sec from 0 to 90 deg). The larger tables give only the logarithms of the functions, not the natural values.

To Find Any Function of a Given Angle. (Reduction to the first quadrant.) It is often required to find the functions of any angle x from a table that includes only angles between 0 and 90 deg. If x is not already between 0 and 360 deg, first "reduce to the first revolution" by simply adding or subtracting the proper multiple of 360 deg [for any function of (x) = the same function of $(x \pm n \times 360°)$]. Next reduce to the first quadrant as follows:

If x is between		90° and 180°	180° and 270°	270° and 360°
Subtract		90° from x	180° from x	270° from x
Then	$\sin x$	$= +\cos(x-90°)$	$= -\sin(x-180°)$	$= -\cos(x-270°)$
	$\csc x$	$= +\sec(x-90°)$	$= -\csc(x-180°)$	$= -\sec(x-270°)$
	$\cos x$	$= -\sin(x-90°)$	$= -\cos(x-180°)$	$= +\sin(x-270°)$
	$\sec x$	$= -\csc(x-90°)$	$= -\sec(x-180°)$	$= +\csc(x-270°)$
	$\tan x$	$= -\cot(x-90°)$	$= +\tan(x-180°)$	$= -\cot(x-270°)$
	$\cot x$	$= -\tan(x-90°)$	$= +\cot(x-180°)$	$= -\tan(x-270°)$
	$\text{vers}\, x$	$= 1+\sin(x-90°)$	$= 1+\cos(x-180°)$	$= 1-\sin(x-270°)$
	$\text{covers}\, x$	$= 1-\cos(x-90°)$	$= 1+\sin(x-180°)$	$= 1+\cos(x-270°)$

The "reduced angle" ($x - 90°$, or $x - 180°$, or $x - 270°$) will in each case be an angle between 0° and 90°, whose functions can then be found in the table.

[NOTE. The formulæ for sine and cosine are best remembered by aid of the unit circle.]

To Find the Angle When One of Its Functions is Given. In general, there will be two angles between 0 and 360 deg corresponding to any given function. The following tabulated rules show how to find those angles.

Given	First find from the tables an *acute* angle x_0 such that	Then the required angles x_1 and x_2 will be
$\sin x = +a$	$\sin x_0 = a$	x_0 and $180° - x_0$
$\cos x = +a$	$\cos x_0 = a$	x_0 and $[360° - x_0]$
$\tan x = +a$	$\tan x_0 = a$	x_0 and $[180° + x_0]$
$\cot x = +a$	$\cot x_0 = a$	x_0 and $[180° + x_0]$
$\sin x = -a$	$\sin x_0 = a$	$[180° + x_0]$ and $[360° - x_0]$
$\cos x = -a$	$\cos x_0 = a$	$180° - x_0$ and $[180° + x_0]$
$\tan x = -a$	$\tan x_0 = a$	$180° - x_0$ and $[360° - x_0]$
$\cot x = -a$	$\cot x_0 = a$	$180° - x_0$ and $[360° - x_0]$

The angles enclosed in brackets lie outside the range 0 to 180 deg, and hence cannot occur as angles in a triangle.

For solution of trigonometric equations, see p. 118.

Selsyn telemotor. These units have both transmitter and receiver alike for interchangeability of spares, single-phase stators, and three-phase rotors, with a minimum of cables between stations. The primary runs at 440 volts, and the rotor windings are interconnected. Any movement of the transmitter rotor is duplicated exactly back aft in the steering engine-room receiver. The unit must have sufficient torque to prevent the units from pulling out of step when the helmsman turns the wheel quickly. Ten turns of the wheel will be normally required for putting the rudder hardover to hardover through

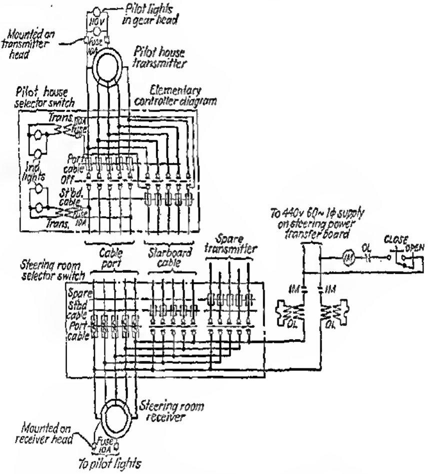

Fig. 16.—Schematic control diagram for electric telemotor.

70 deg. Figure 16 shows a specimen schematic wiring diagram for one of these units. The transmitter is located vertically in the case of each steering stand, and the receiver is located in the steering engine room, near the stroking control of the pumps. Follow-up motion from the rudder movement itself governs the system. An overload line contactor and line selector switch are necessary, there being duplicate cables run between stations. As the selector switch in the pilothouse, with its indicating lamps, is duplicated aft, the cable selection can be controlled from the steering engine room as well.

Design and Layout. The top wheelhouse steering stand, a nonmagnetic design, is connected mechanically to the wheelhouse telemotor transmitter by shaft, clutch, and gears. The aft steering station has a nonmagnetic

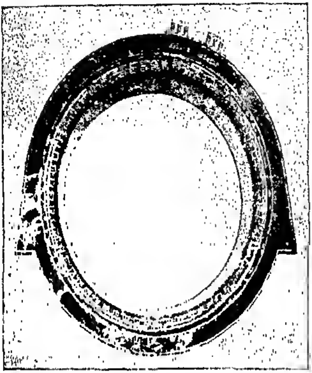

FIG. 8—Stator for synchronous marine motor. *(Courtesy of General Electric Company.)*

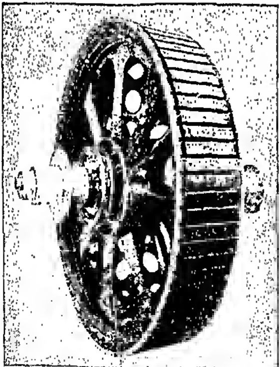

FIG. 9.—Revolving field for synchronous marine motor. *(Courtesy of General Electric Company.)*

stand also, mechanically connected to the trick stations are required by the U.S. Coast Guard, Merchant Marine Inspection Division.

The Sperry gyro-pilot system, if fitted, embodies the following: steering stand in wheelhouse; servo-power unit; transfer switches; and motor-control panel all in the steering engine room, and two d-c–a-c, 110-volt, 60-cycle, motor generator sets. The gyro pilot also has a repeater for the helmsman, a rudder-angle indicator graduated in degrees, adequate lighting provisions, and adjustments for various weather and rudder conditions. The control should be able to disconnect the system entirely, put it on automatic steering, or put it on hand steering. The rudder-angle indicator should be accurate to within ½ deg from the indicated setting. The gyro-pilot power unit should not need any means of supplementary torque amplification but should stroke either or both the main pumps directly. Limit switches should be provided to control the hardover rudder settings at nominal 35 deg settings. When steering by gyro, the hydraulic system should be completely by-passed.

Control. The steering wheel, usually between 36 to 42 in. in diameter, must turn to the right to turn the vessel's rudder and the bow to the right; conversely, it turns left to turn the ship to the left. The words **port** and **starboard** are no longer used in giving steering directions owing to the possibility of confusion of intent in emergencies, such as the collision between the "Mohawk" and the "Talisman," which resulted when the telemotor liquid froze and the emergency signals were misunderstood on the "Mohawk." The rudder indicator must have an adjustable pointer and graduations 35 deg left and right. No more than 10 or 15 turns should be necessary to put the rudder through 70 deg.

The specifications should clearly include complete operating and lubrication instructions for the entire steering system to be posted in the steering room. These should be clearly posted and should include complete directions for all conditions of operation, especially those movements required to shift over to emergency steering.

attained when the countertorque applied does not cause propeller cavitation. In reversing a synchronous motor on its induction motor winding, the opposing torque gradually brings the propeller to rest without causing undue stresses in the line shafting.

In one of the first synchronous motor applications, an experiment was made in which the generator and motor fields were removed, the main line contactors reversed, the slip rings of the generator short-circuited, and the field current then applied to the motor only. This operation was performed with the turbine-speed lever in the maneuvering position. This caused the motor to act as a generator and the generator as an impedance, thereby occasioning a dynamic braking action. A more effective method of dynamic braking is attained by temporarily inserting resistors across the motor terminals until the high peak of propeller torque caused by the ship's driving action is overcome.

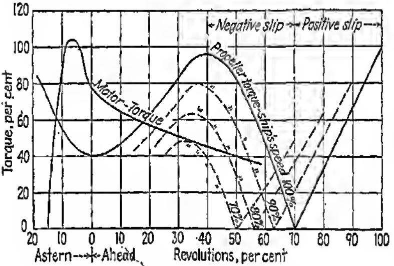

FIG. 10.—Propeller-torque curve during reversal of propeller with ship maintaining constant-ahead speed.

Power Required during Reversal. When a ship is being driven ahead and the power to the propeller is disconnected, zero torque on the propeller will take place when the propeller slip decreases to zero. The exact speed corresponding to zero torque being a function of actual slip, it will differ on vessels having different propellers and wake factors. Usually, this point corresponds to approximately 70 percent of the ahead revolutions corresponding to the ship's speed.

In applying power to reverse the propeller, the ship's coasting speed has a tendency to keep the propeller revolving in the ahead direction and, if sufficient retarding torque is applied to create a negative slip equal to the positive slip corresponding to that attained when driving the ship in the ahead direction, the torque will be approximately equal.

The percentage of the ahead revolutions at which maximum negative torque is attained when dynamically braking the forward movement of the propeller varies widely on different classes of vessels, and also on identical vessels operating at different drafts. The factors that influence the brak-

ELECTRIC SHIP PROPULSION

BY

FRANK V. SMITH

TURBINE-ELECTRIC DRIVE

Classification of System. The term "turbine-electric drive" designates a form of ship-propulsion apparatus in which a steam-turbine-driven generator is used to furnish power to a propelling motor. In installations using a-c generators and motors, propeller reversals are accomplished by a switching of electrical connections between the generator and the motor; speed changes are effected by altering the speed of the prime mover. In installations using d-c generators and motors, speed changes are made by altering the voltage, and reversals are made by changing the direction of current flow. Both of these functions are controlled by the generator field.

With few exceptions, a-c generators and motors have been used in turbine-electric-drive installations—the few d-c installations being mainly of historical interest.

Type of Electrical Apparatus Used. During the developmental stages of turbine-electric drive, induction motors of the squirrel-cage type were used. Notable examples of this type were found on the U.S.S. "Jupiter" (later renamed the "Langley")—the first large ship to be electrically propelled; the U.S. Navy battleship "New Mexico"; and the U.S. Navy airplane carriers, the "Saratoga" and "Lexington."

In modern practice, the synchronous type of a-c motor is almost universally used because of its lighter weight, higher efficiency, and unity power-factor characteristics.

The complete apparatus, considered from the standpoint of a single propelling unit, consists of

1. Steam turbine of the condensing type directly connected to a three-phase a-c generator.
2. Propelling motor of the synchronous type mechanically constructed for direct connection to the propeller shaft.
3. Control panel upon which are mounted the levers for operating the reversing contactors; generator and motor field contactors; and turbine speed control.
4. Exciter generator for furnishing direct current to the generator and motor field circuits.

Primary Purpose and Inherent Advantages. Turbine-electric drive is used primarily to effect a reduction in speed between a high-speed prime mover and a slow-speed propeller. Within certain limitations turbine-electric drive permits a satisfactory fixed speed-reduction ratio between the two for the attainment of a high over-all propulsive efficiency.

The inherent advantages are as follows:

1. The turbine generator on certain types of ships can be used as a universal power plant, thereby eliminating the duplication of powering equipment for loading and unloading operations and for special power purposes.
2. In ships having multiple generating equipments and propeller shafts, electrical connections can be provided that permit the paralleling of motors on a single generator under reduced power conditions.

ing torque during the deceleration period are (1) the stern design of the hull and (2) the tendency of the propeller to cavitate. Both of these items change with the draft and trim of the vessel.

When a ship is operated in the astern direction, the thrust column of water from the propeller flows forward against the hull of the vessel thereby partly canceling the effectiveness of the astern thrust caused by the propeller. The rate of revolutions at which normal rated propeller torque in the astern

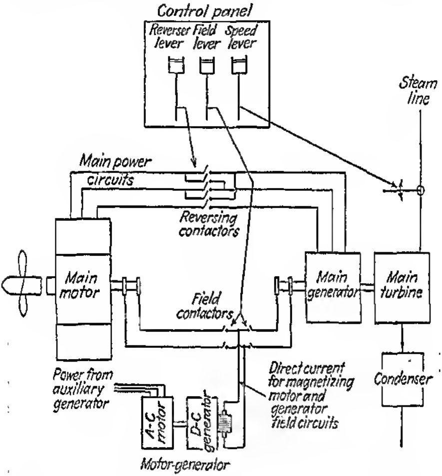

Fig. 11.—Fundamental control and power circuits for turbine-electric drive system.

direction is attained varies on different types of vessels and differs appreciably between single-screw vessels and vessels with wing screws.

A typical propeller-torque curve during reversal based on the assumption that the ship's speed remains constant at 100 percent in the forward direction is shown in Fig. 10. In practice a ship decelerates very rapidly from its top speed, and as its speed is reduced the negative torque that must be applied to the propeller to cause its reversal also decreases very rapidly. If it is assumed that propeller slip is as effective in producing torque on one side of the propeller blading as the other, then the retarding torque required to reverse the propeller is a function of the ship's speed at the time of reversal. Actually, the back of the blade is not so effective as is the face.

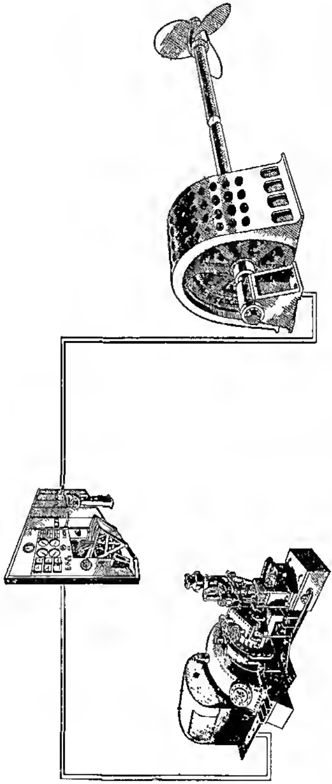

FIG. 1.—Turbine-generator set, control board, and synchronous motor, main items in marine turbine-electric drive. (*Courtesy of General Electric Company.*)

To drive a ship ahead at 100 percent speed requires 100 percent torque on the propeller. Assuming torque to vary as the square of the revolutions, approximately 81 percent torque is required at 90 percent speed; 64 percent at 80 percent speed; and 49 percent at 70 percent speed.

In reversing a propeller by means of a motor, the designer is interested in knowing the time element involved in a ship's deceleration as well as the peak of the torque curves during reversal. Very few ships have the same reversing torque characteristics, and it is general practice when ships go into commission to take extensive oscillograph records during crash reversals, and all other conditions of operation.

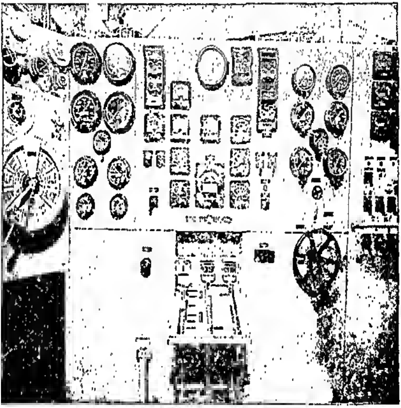

FIG. 12.—General Electric propulsion control panel on 10,000 shp tanker.

This accumulation of design information acts as a guide in considering new designs and in adequately designing the electrical characteristics of the motor to effect proper retarding effect and synchronization after the motor has attained its slip speed as an induction motor in the reverse direction.

Pulsating power loads caused by heavy seas vary widely. At one instant the propeller may emerge from the water resulting in zero torque, and at the next instant it may be submerged deeply. A complete understanding of the torque speed characteristics of the propeller under all conditions of operation is necessary before the electrical design factors can be chosen (see p. 1425 Propellers Backing or in Reverse).

Control of Turbine-electric Drive. From an operative point of view, there are four functions to be considered as follows:

3. Flexibility of power arrangement. The turbine-generator location in the ship can be made independently of the location of the propelling motor.

4. Ease and rapidity of maneuvering electrical connections can be quickly switched for propeller reversal without altering the direction of rotation of the prime mover.

5. Maximum power available for astern operation.

6. Improved relation between propeller speed and torque. Torsional vibrations that emanate from the propeller are not transmitted to the prime mover, or are reduced.

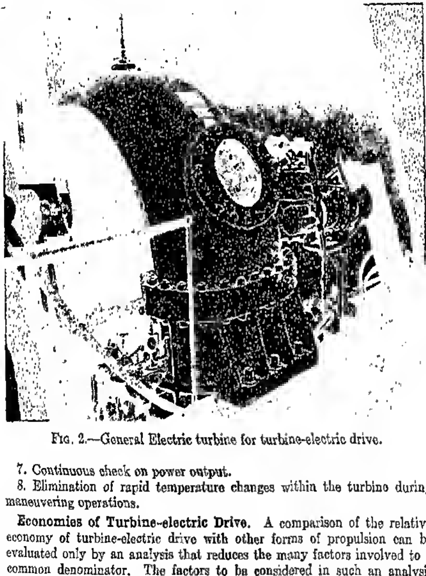

FIG. 2.—General Electric turbine for turbine-electric drive.

7. Continuous check on power output.

8. Elimination of rapid temperature changes within the turbine during maneuvering operations.

Economies of Turbine-electric Drive. A comparison of the relative economy of turbine-electric drive with other forms of propulsion can be evaluated only by an analysis that reduces the many factors involved to a common denominator. The factors to be considered in such an analysis consist of the specific type of ship, its proposed trade route, speeds between ports of call, space and weight factors, auxiliary power needs, first cost and resultant capital charges, depreciation, operating charges, and fuel costs at ports of call.

The foregoing type of analysis is made by computing a complete heat balance for a specific type of ship, taking into consideration the extraneous

1. Turbine-generator speed control.
2. Switching of power leads for propeller reversal.
3. Means for closing switches in generator and motor field circuits in proper sequence.
4. Means for varying generator and motor field current to suit the power and speed conditions.

In modern marine practice functions (1), (2), and (3) are controlled by two levers situated on the control panel. Function (4) may be either manually or automatically controlled. One lever called the reversing and field lever combines functions (2) and (3) and is supplied with three posi-

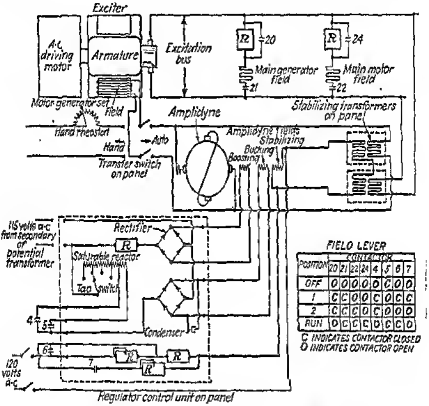

FIG. 13.—Amplidyne schematic wiring diagram.

tions in both the ahead and the astern position. Position one on this lever closes the main-line contactors for the ahead or reverse operation as desired; position 2 closes the generator field switch; and position 3 closes the motor field switch. The second lever controls the speed of the turbine, and interlocking arrangements are provided which make it necessary to return the speed lever to a predetermined maneuvering position before moving the field and reversing lever.

In the earlier turbine-electric-drive installations functions (1), (2), and (3) were controlled by separate levers. Interlocking arrangements were provided which made it necessary to open the field circuits prior to opening or closing the main-line switches.

The motor and generator field current was manually controlled by means of rheostats in the earlier installations. Power-factor meters and excitation

apparatus found necessary with each form of drive. This shows the fuel rates per shaft horsepower per hour for all purposes, which can be quickly interpreted into terms of nautical miles per ton of fuel if the propulsive efficiency is known (see p. 1267).

The fuel rate on a ship is dependent upon the design factors of the power plant, such as boiler efficiency, steam pressure and superheat, vacuum obtainable with sea temperatures existing on a given trade route, type of heat-recovery apparatus installed, type and efficiency of auxiliary apparatus, and magnitude of auxiliary power needs.

Because of the unidirectional rotation characteristics of the turbine on electric-drive ships, such turbines are especially adapted for making use of high-pressure, high-temperature steam, and also for the inclusion of steam-extraction systems for multiple-stage feed-water heating.

The transmission efficiency between the turbine and the propeller shaft is a function of the designed horsepower output of the equipment. In the smaller powers an average of 92 to 93 percent is generally obtainable, increasing to as high as 96.2 percent in the larger powers. The transmission efficiency has an almost flat characteristic over a very wide range of loads. This is due to the core and windage losses being reduced approximately in proportion to the square of the frequency.

Turbine efficiency is the function of its speed, number of stages, steam conditions, and power output. In cases where it has not been necessary to compromise any of these factors, the maximum efficiency is obtained. Whether it pays to design for minimum steam consumption, however, depends upon a correct evaluation of the many other pieces of apparatus that operate within the power cycle.

Types of Ships to Which Adapted. High-powered passenger ships and combination passenger-cargo ships of the twin-screw and quadruple-screw type offer the most advantageous field for turbine-electric drive. It is in this field that the turbine generator designers and motor-designing engineers can cooperate freely with naval architects in obtaining the most economic results. There are no design limitations to the amount of power that can be applied, and by using motors in tandem (if necessary) on a propeller shaft 50,000 hp per shaft and above can be as readily applied as motors of lesser rating.

Cargo ships and tankers lie within the natural province of turbine-electric drive provided the special features of the system so warrant, and the nominal horsepower range is 5,000 hp or above. In tankers, use can be made of the main generating equipment to drive motor-driven cargo oil pumps of large capacity, without duplication of powering equipment. Many types of self-unloading bulk-freight carriers can also make use of the main power plant in port under special conditions.

Naval vessels can best meet special maneuvering requirements by means of turbine-electric drive.

The turbine speed should be selected with reference to the generator speed after a satisfactory speed-reduction ratio between the generator and the motor speed has been selected. In installations that make use of the main propulsion generators for auxiliary purposes in port, 60-cycle current is generally preferable, which with a two-pole generator gives a resultant speed of 3,600 rpm. This does not restrict the turbine generator from operating on a variable-frequency basis when driving the propelling motor alone, but it may influence the normal designed operating speed, especially if the auxiliary power requirements in port are of sufficient magnitude.

indicators were furnished on the control panel for the operator's guidance. In the modern installations, this function is automatically controlled by means of an amplidyne generator whose power output controls the field of the exciter generator. The fields of the amplidyne are controlled by means of a voltage regulator that functions to maintain the proper relationship between the voltage and the frequency, thereby providing a sufficient margin of motor torque to keep the synchronous propelling motor in step even under pulsating load conditions.

The amplidyne generator is similar in appearance to a d-c generator except that it has one pair of brushes short-circuited. The amplification factor between the field and the armature circuit is extremely high, being in the order of 10,000: 1. The small amount of current needed for the amplidyne

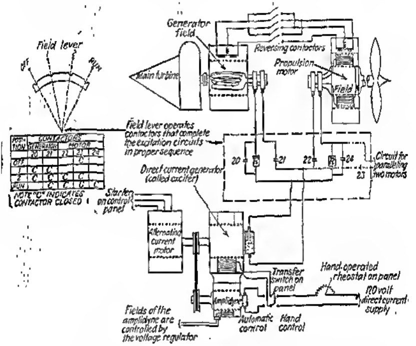

FIG. 14.—Amplidyne control showing power circuits.

fields is furnished by a small transformer from the main power circuit and converted to direct current by means of small rectifiers. The general system in use is shown in Figs. 13 to 14.

DIESEL-ELECTRIC DRIVE USING DIRECT-CURRENT MACHINERY

Classification. Diesel-electric drive is a form of propulsion in which a generator and a motor are interposed between the prime mover and propeller shaft for purposes of speed reduction and maneuverability. Direct-current generators and motors have been almost universally used in connection with diesel-electric drive, because of the variable-speed-reduction characteristic that can be obtained. This characteristic permits the operation of the diesel engine at its most advantageous speed considered from the standpoint of torque and exhaust temperatures irrespective of the pro-

Generators.—In practically all modern turbine-electric-drive installations the a-c generators are of the three-phase, two-pole, Y-wound type. The two-pole type of generator is used because it permits the highest speed-reduction ratio between the turbine generator and the propelling motor and permits the

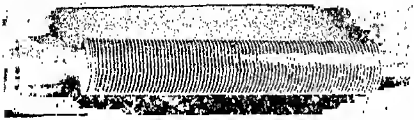

FIG. 3.—Fin tube for General Electric surface air cooler.

maximum turbine speed with the minimum number of poles on the motor. This speed-reduction ratio is a direct proportion of the number of poles on the motor to the number of poles on the alternator and is fixed, once it is selected.

The generators are usually directly connected to the turbines, forming a three-bearing set, and totally enclosed for protection against dust or oil-

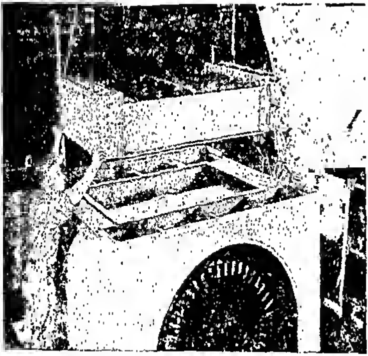

FIG. 4.—Top-mounted surface air cooler for turbine generator. (*Courtesy of General Electric Company.*)

sludge deposit on the windings. In this type of construction air coolers are provided on either the upper or the lower section of the casing, and the air is recirculated through the generator and cooler by means of a fan directly connected to the generator rotor. The coolers use circulating water as the medium for carrying away the heat.

peller speed, and the inclusion of one or a multiple number of diesel-engine-driven generators within the power loop to satisfy a specific power demand.

Type of Electrical Apparatus Used. Direct-current generators of the separately excited shunt-field type are almost universally used with diesel-electric drive in conjunction with the variable voltage system of control. In a few instances the constant-voltage system has been adopted on special types of ships but they have been few in number and are of minor importance.

The complete electrical apparatus considered from the standpoint of a single unit consists of the following:

1. Direct-current generator arranged for direct coupling to a diesel engine.
2. Direct-current motor for direct coupling to the propeller shaft. In the high-power range, two direct-drive motors mounted in tandem on a common shaft (called a double-armature motor), or two motors driving the shaft through gearing are used.
3. Exciter-generator: There are several methods of furnishing exciting current for the generator and motor field poles; among those fulfilling the majority of applications are the following:

   a. From the ship's auxiliary power bus.
   b. From an overhung type of d-c generator driven from an extension of the main generator shaft.
   c. From a motor-generator set.

   NOTE. Types (b) and (c) are adapted to main generator voltage control through control of the exciter field. This results in a system of control that uses a very small amount of current in the speed controllers but does require a separate source of excitation for the motor field.

4. Main-control panel upon which are mounted the switches, speed controllers, meters, rheostats, and instruments for making operational checks.
5. Speed controllers for mounting on the bridge. This item is optional.

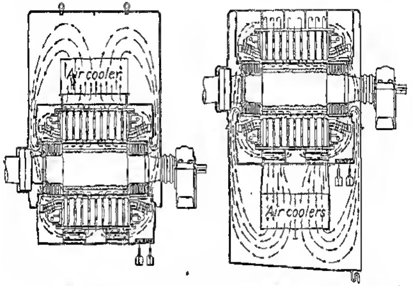
Claimed Advantages of Diesel-electric Drive.

1. Flexibility with relation to placement of powering units in ship.
2. Main propulsion units can be used for dual purposes. When the constant-voltage system is used, the units can be employed simultaneously to furnish power for propulsion and the ship's auxiliaries. When the variable-voltage system is used, units can be withdrawn from the propulsion-power loop for special power purposes at sea or used to furnish power for large auxiliary-power loads in port.
3. The installation of a multiple number of powering units permits a machine to be taken out of service at sea for repair or overhaul.
4. Rapidity and ease of control from any location desired.
5. Increase of propulsive efficiency because of independent selection of engine speed and propeller speed.
6. Adjustment of propeller speed-torque relationship for absorption of normal rated horsepower of engines under varying load conditions.
7. Low stand-by losses.
8. Elimination of excessive torque on engines during surging power loads, thereby preventing high exhaust temperatures.
9. Smooth deceleration and acceleration during reversal, without altering direction of rotation of engines.
10. Engines can be properly warmed up prior to ship's operation.

The devices that protect against electrical faults on such generators consist of unbalanced phase relays and ground relays. Each of these devices removes the field from the generator and motor in case of faults on the system.

The instruments used for observation of the operating conditions consist of ammeters, voltmeters, and temperature indicators. The temperature measurement of the stator windings is made by means of temperature detectors embedded among the windings in each phase. It is also the accepted practice to install heaters in the casing so that the temperature within it can be maintained above room temperature when the machine is stationary and thus avoid condensation on the windings.

Propelling Motors. The synchronous type of polyphase motor is in general use on modern ships. During the developmental stages of turbine-



AIR COOLER MOUNTED ON TOP OF GENERATOR AIR COOLER INSTALLED BELOW THE FLOOR

Fig. 5.—Air cooler in operation.

electric drive induction motors with pole-changing characteristics were used to attain different speed ratios between the generator and the motor, but these are now of only slight interest. The higher efficiency and lighter weight of the synchronous motor, in comparison to either the squirrel-cage or wound-rotor type of induction motor, and its unity power-factor characteristic, which greatly lessens the physical dimensions of the generator, more than offset the advantages of correction in turbine speed at low powers.

The speed-reduction ratio that can be accomplished, when the propelling motor is directly connected to the propeller shaft, is a function of its number of poles, and this in turn is restricted by the diameter of the motor that can be installed in a given ship.

The synchronous type of motor as developed for ship propulsion utilizes a heavy squirrel-cage winding for starting and reversing operations. This winding is embedded in the faces of the rotor field poles and becomes inactive after the motor is brought into synchronism. In first accelerating the motor

Operating Principle. With constant field excitation the speed of a shunt motor varies almost directly with the applied voltage, and the direction of rotation with the direction of the current through the armature. As the armature current is a function of the applied voltage and counter emf produced by the field, the torque-speed relationship of this type of motor can be closely adjusted by regulating either the line voltage or the field excitation.

The voltage produced by a generator is a function of its speed, and the magnetic intensity of its field poles. With constant field excitation, the armature voltage varies directly with the revolutions, and at a constant rate of revolutions the voltage varies almost directly with the field current. The polarity at the armature terminals depends upon the direction of current flow through the generator field coils.

In applying diesel-electric drive, the designer has two systems of control from which to choose: (1) the variable-voltage system and (2) the constant-voltage system. The choice between the two is dependent upon the use of the generator at sea.

In installations that use the main propulsion generators exclusively for propulsive power at sea, the variable-voltage system is preferable because it permits both the rate of propeller revolutions and the direction of rotation to be controlled by the generator field excitation. This does not prevent such a generator, however, from being removed from the propulsion circuit at sea for special power purposes or from being used in port as a constant potential unit. Several ingenious methods have been used in modern installations to vary the field current to the main generators efficiently with minimum loss in the field resistors. This has been accomplished by installing a small generator for furnishing excitation to the main generator or generators only and by varying the field of this smaller generator.

In the constant-voltage system of control, speed variations are obtained by means of resistors in the armature circuit, and reversals by a switching of the armature leads. This system results in an appreciable power loss if the motor is to be operated at reduced speed continuously and is therefore applicable only to ships that operate at their designed speed the greater part of the time.

Application of Variable-voltage System of Control. Because of the ease with which diesel-electric drive can be controlled through the generator field alone, the system is adaptable to bridge control, engine-room control, or from any location desired. The apparatus used to control this function consists of a variable resistor and reversing contactors, which can be easily operated by means of a single wheel or lever.

In the earlier installations it was the general practice to operate the diesel engine at a constant speed throughout the power range and to vary the generator field strength to effect speed changes. In view of the fact that a ship's power varies as the cube and greater exponents of the speed and the propeller torque approximately as the square of the revolutions, the high engine speeds are not compatible with good efficiency in the low power range.

In the modern types of installations it is general practice to operate the engines at half speed, at propeller speeds below 50 percent speed, and to effect speed changes in this range by means of the generator field excitation. At speeds above 50 percent the excitation is held constant, and the voltage that affects the motor speed is regulated by means of the diesel-engine speed. This type of control has a very beneficial effect on the engines. If a heavy surging power load is imposed on the propeller, the additional current required

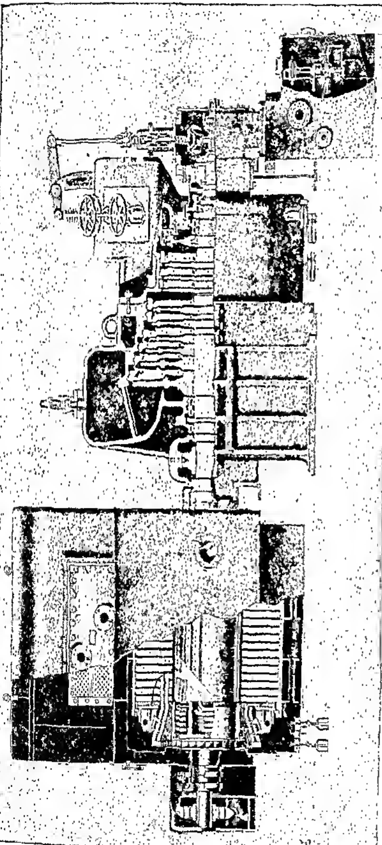


FIG. 6.—Turbine-generator set for ship propulsion. (*Courtesy of General Electric Company.*)

to meet this torque is reflected back to the engine, in which case the speed of the engine is reduced, thereby reducing the voltage and propeller revolutions. As current and torque are proportional and the torque can be controlled by the motor *field rheostat*, the system lends itself to a wide range of propeller torque-speed relationships, without imposing torques above normal on the engine. Figure 15 shows the revolutions, torque, and voltage characteristics.

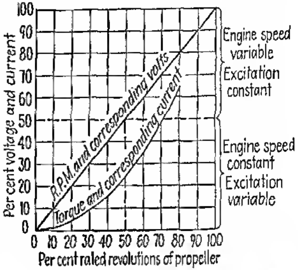

FIG. 15.—*Rpm, torque,* and voltage characteristics of d-c marine drive.

Types of Ships to Which Adapted. The development of relatively high-speed, high-powered diesel engines is continually opening up new fields for marine propulsion application when combined with an electric form of variable-speed reduction between the prime mover and the propeller shaft.

The types of ships to which diesel-electric drive is best adapted are those which require 2,500 hp or less per propeller shaft, and in which the duty and maneuvering requirements cover a wide range. Another factor that may have an equal bearing on the selection of diesel-electric drive is the ability to use the main power units for auxiliary power purposes in port, or a portion of the units at sea for special power purposes.

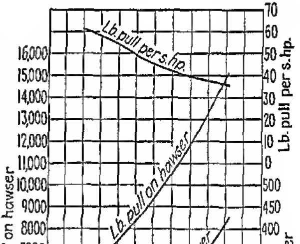

FIG. 16.—Standstill tests of tugboat "Van Dyke 1."

Towboats, seagoing tugs, tankers, small passenger vessels, cargo ships, ferries, salvage vessels, submarines, net tenders, minesweepers, tenders, repair ships, self-propelled dredges, canal boats, self-

up to its slip speed as an induction motor prior to synchronization, the system voltage is increased by temporarily increasing the generator field excitation.

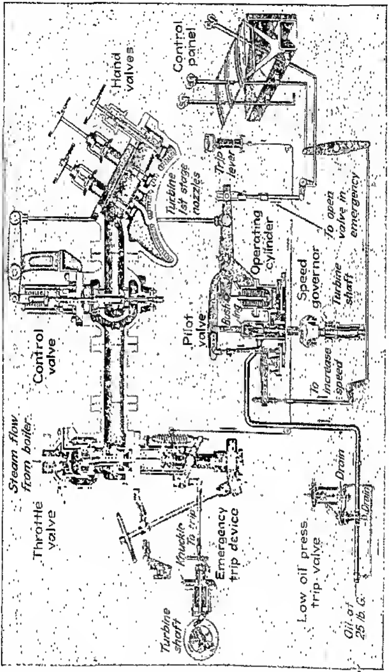

FIG. 7.—Governing system for General Electric steam-turbine ship-propulsion system.

In reversing a ship's propeller the main objective is to bring the ship to rest in the shortest length of time, rather than the propeller. This is usually

unloading bulk-freight carriers, refrigerator ships, and many special types of ships all lie within the natural province of diesel-electric-drive application.

Tugboats. The variable-speed-reduction characteristic of diesel-electric drive makes it especially adaptable to tug boats. The ability to utilize the full rated power output of the engines from standstill to full-speed running light, without imposing above-normal torque on the diesel engines, results in the maximum towing efficiency. The propeller can also be designed especially for towing, thereby resulting in an appreciable gain in propulsion efficiency.

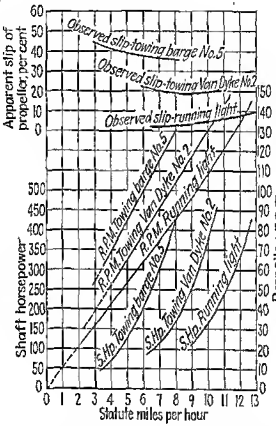

FIG. 17.—Towing tests of tugboat "Van Dyke 1."

The extremes met with in tugboat service range from the condition existing when first accelerating a tow, in which the propeller apparent slip is 100 percent and all of the power is expended in exerting a dead pull on the hawser, to the running-light condition in which all of the power is expended in propelling the boat. Knowledge concerning the torque-speed relationship of the propeller, between the two extremes of power expenditure, is of vital concern to the designer, as it enables him to predict with a degree of certainty the division of power available for towing and to calculate the value of towing efficiency.

A series of tests made on the diesel electrically propelled tugboat "Van Dyke 1," showing the complete characteristics over the entire power range,

Relations Between the Functions of a Single Angle. (See Fig. 5.)

$\sin^2 x + \cos^2 x = 1$; $\tan x = \dfrac{\sin x}{\cos x}$; $\cot x = \dfrac{1}{\tan x} = \dfrac{\cos x}{\sin x}$;

$1 + \tan^2 x = \sec^2 x = \dfrac{1}{\cos^2 x}$; $1 + \cot^2 x = \csc^2 x = \dfrac{1}{\sin^2 x}$;

$\sin x = \sqrt{1 - \cos^2 x} = \dfrac{\tan x}{\sqrt{1 + \tan^2 x}} = \dfrac{1}{\sqrt{1 + \cot^2 x}}$;

$\cos x = \sqrt{1 - \sin^2 x} = \dfrac{1}{\sqrt{1 + \tan^2 x}} = \dfrac{\cot x}{\sqrt{1 + \cot^2 x}}$.

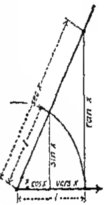

Fig. 5.

Functions of Negative Angles. $\sin(-x) = -\sin x$; $\cos(-x) = \cos x$; $\tan(-x) = -\tan x$.

Functions of the Sum and Difference of Two Angles.

$\sin(x + y) = \sin x \cos y + \cos x \sin y$;
$\cos(x + y) = \cos x \cos y - \sin x \sin y$;
$\tan(x + y) = [\tan x + \tan y]/[1 - \tan x \tan y]$;
$\cot(x + y) = [\cot x \cot y - 1]/[\cot x + \cot y]$;
$\sin(x - y) = \sin x \cos y - \cos x \sin y$;
$\cos(x - y) = \cos x \cos y + \sin x \sin y$;
$\tan(x - y) = [\tan x - \tan y]/[1 + \tan x \tan y]$;
$\cot(x - y) = [\cot x \cot y + 1]/[\cot y - \cot x]$;
$\sin x + \sin y = 2 \sin \tfrac{1}{2}(x + y) \cos \tfrac{1}{2}(x - y)$;
$\sin x - \sin y = 2 \cos \tfrac{1}{2}(x + y) \sin \tfrac{1}{2}(x - y)$;
$\cos x + \cos y = 2 \cos \tfrac{1}{2}(x + y) \cos \tfrac{1}{2}(x - y)$;
$\cos x - \cos y = -2 \sin \tfrac{1}{2}(x + y) \sin \tfrac{1}{2}(x - y)$;

$\tan x + \tan y = \dfrac{\sin(x + y)}{\cos x \cos y}$; $\cot x + \cot y = \dfrac{\sin(x + y)}{\sin x \sin y}$;

$\tan x - \tan y = \dfrac{\sin(x - y)}{\cos x \cos y}$; $\cot x - \cot y = \dfrac{\sin(y - x)}{\sin x \sin y}$;

$\sin^2 x - \sin^2 y = \cos^2 y - \cos^2 x = \sin(x + y) \sin(x - y)$;
$\cos^2 x - \sin^2 y = \cos^2 y - \sin^2 x = \cos(x + y) \cos(x - y)$;
$\sin(45° + x) = \cos(45° - x)$; $\tan(45° + x) = \cot(45° - x)$;
$\sin(45° - x) = \cos(45° + x)$; $\tan(45° - x) = \cot(45° + x)$.

In the following transformations, a and b are supposed to be positive, $c = \sqrt{a^2 + b^2}$, A = the positive acute angle for which $\tan A = a/b$, and B = the positive acute angle for which $\tan B = b/a$:

$a \cos x + b \sin x = c \sin(A + x) = c \cos(B - x)$;
$a \cos x - b \sin x = c \sin(A - x) = c \cos(B + x)$.

Functions of Multiple Angles and Half Angles.

$\sin 2x = 2 \sin x \cos x$; $\sin x = 2 \sin \tfrac{1}{2}x \cos \tfrac{1}{2}x$;
$\cos 2x = \cos^2 x - \sin^2 x = 1 - 2 \sin^2 x = 2 \cos^2 x - 1$;

$\tan 2x = \dfrac{2 \tan x}{1 - \tan^2 x}$; $\cot 2x = \dfrac{\cot^2 x - 1}{2 \cot x}$;

$\sin 3x = 3 \sin x - 4 \sin^3 x$; $\tan 3x = \dfrac{3 \tan x - \tan^3 x}{1 - 3 \tan^2 x}$;

$\cos 3x = 4 \cos^3 x - 3 \cos x$;

$$\sin(nx) = n \sin x \cos^{n-1} x - (n)_3 \sin^3 x \cos^{n-3} x + (n)_5 \sin^5 x \cos^{n-5} x - \ . \ . \ . ;$$

$$\cos(nx) = \cos^n x - (n)_2 \sin^2 x \cos^{n-2} x + (n)_4 \sin^4 x \cos^{n-4} x - \ . \ . \ . ,$$

where $(n)_2, (n)_3, \ . \ . \ .$ *are the binomial coefficients* (see p. 39).

$$\sin \tfrac{1}{2} x = \pm \sqrt{\tfrac{1}{2}(1 - \cos x)};\ 1 - \cos x = 2 \sin^2 \tfrac{1}{2}x;$$

$$\cos \tfrac{1}{2}x = \pm \sqrt{\tfrac{1}{2}(1 + \cos x)};\ 1 + \cos x = 2 \cos^2 \tfrac{1}{2}x;$$

$$\tan \tfrac{1}{2}x = \pm \sqrt{\frac{1 - \cos x}{1 + \cos x}} = \frac{\sin x}{1 + \cos x} = \frac{1 - \cos x}{\sin x};$$

$$\tan\left(\frac{x}{2} + 45°\right) = \pm \sqrt{\frac{1 + \sin x}{1 - \sin x}}.$$

Here the $+$ or $-$ sign is to be used according to the sign of the left-hand side of the equation.

Relations Between Three Angles Whose Sum is 180°.

$$\sin A + \sin B + \sin C = 4 \cos \tfrac{1}{2}A \cos \tfrac{1}{2}B \cos \tfrac{1}{2}C;$$
$$\cos A + \cos B + \cos C = 4 \sin \tfrac{1}{2}A \sin \tfrac{1}{2}B \sin \tfrac{1}{2}C + 1;$$
$$\sin A + \sin B - \sin C = 4 \sin \tfrac{1}{2}A \sin \tfrac{1}{2}B \cos \tfrac{1}{2}C;$$
$$\cos A + \cos B - \cos C = 4 \cos \tfrac{1}{2}A \cos \tfrac{1}{2}B \sin \tfrac{1}{2}C - 1;$$
$$\sin^2 A + \sin^2 B + \sin^2 C = 2 \cos A \cos B \cos C + 2;$$
$$\sin^2 A + \sin^2 B - \sin^2 C = 2 \sin A \sin B \cos C;$$
$$\tan A + \tan B + \tan C = \tan A \tan B \tan C;$$
$$\cot \tfrac{1}{2}A + \cot \tfrac{1}{2}B + \cot \tfrac{1}{2}C = \cot \tfrac{1}{2}A \cot \tfrac{1}{2}B \cot \tfrac{1}{2}C;$$
$$\cot A \cot B + \cot A \cot C + \cot B \cot C = 1;$$
$$\sin 2A + \sin 2B + \sin 2C = 4 \sin A \sin B \sin C;$$
$$\sin 2A + \sin 2B - \sin 2C = 4 \cos A \cos B \sin C.$$

Inverse Trigonometric Functions. The notation $\sin^{-1}x$ (read: antisine of x, or inverse sine of x; sometimes written arc sin x) means the principal angle whose sine is x. Similarly for $\cos^{-1}x$, $\tan^{-1}x$, etc. (The principal angle means an angle between $-90°$ and $+90°$ in case of $\sin^{-1}$ and $\tan^{-1}$, and between 0° and 180° in the case of $\cos^{-1}$.) For graphs, see p. 174.

SOLUTION OF PLANE TRIANGLES

The "parts" of a plane triangle are its three sides, a, b, c, and its three angles A, B, C (A being opposite a, B opposite b, C opposite c, and $A + B + C = 180°$). A triangle is, in general, determined by any three parts (not all angles). To "solve" a triangle means to find the unknown parts from the known. The fundamental formulæ are:

Law of sines: $\dfrac{a}{b} = \dfrac{\sin A}{\sin B}$. Law of cosines: $c^2 = a^2 + b^2 - 2ab \cos C$.

Right Triangles. Use the definitions of the trigonometric functions, selecting for each unknown part a relation which connects that unknown with known quantities; then solve the resulting equations. Thus, in Fig. 6, if $C = 90°$, then $A + B = 90°$, $c^2 = a^2 + b^2$,

FIG. 6.

$$\sin A = a/c,\ \cos A = b/c,\ \tan A = a/b,\ \cot A = b/a.$$

If A is very small, use $\tan \tfrac{1}{2}A = \sqrt{(c - b)/(c + b)}$.

Oblique Triangles. There are four cases. It is highly desirable in all these cases to draw a sketch of the triangle approximately to scale before commencing the computation, so that any large numerical error may be readily detected.

Case 1. GIVEN TWO ANGLES (provided their sum is $<$ 180 deg), AND ONE

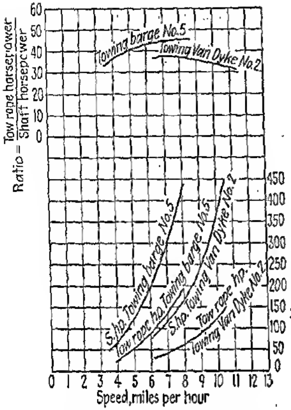

Fig. 18.—Towing tests of tugboat "Van Dyke" 1.

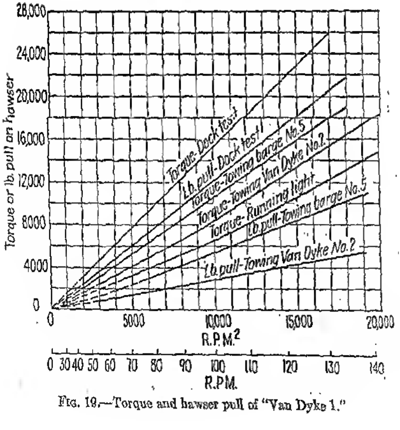

Fig. 19.—Torque and hawser pull of "Van Dyke 1."

usually present in the field of a synchronous motor. This element is provided with removable end bells which serve to make the entire unit drip-proof, and it also supports the brush rigging associated with the collector rings of the engine element.

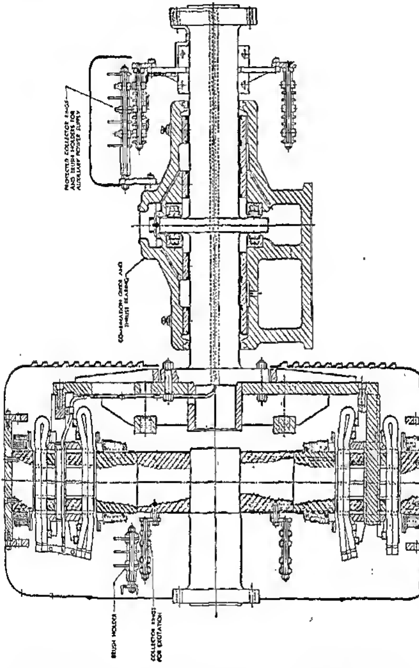

Fig. 1.—Bowes drive.

Operation. The Bowes drive is operated in the following manner: With the engine running at its idling speed, excitation is supplied to the engine element. This sets up a rotating magnetic field which moves past the winding on the inner periphery of the shaft element and generates a voltage in this winding exactly as in the case of the conventional generator. As

are shown in Figs. 16 to 20. This boat is rated 375 shp at 140 rpm running light.

Figure 16 shows the pounds pull on the hawser at standstill of the boat. With the propeller operating at 100 percent apparent slip, rated full power was expended at 107 rpm, or 76.5 percent rated revolutions.

Figure 17 shows the shaft horsepower, revolutions, and observed propeller slip, under a heavy towing condition, light towing condition, and under free-running condition. Figure 18 shows the percentage of power available for towing under light- and heavy-towing conditions. As the "Van Dyke 2," which constituted the light tow, was similar in every respect to the "Van Dyke 1," it is possible to deduce from this test the actual hull resistance or thrust required to drive this ship, and ascertain with a fair degree of accuracy the propulsive efficiency of either boat. Running free, the "Van Dyke 1" required 200 hp to obtain a speed of 10.5 mph, whereas the "Van Dyke 2" required 150 tow-rope hp to attain a similar speed. The test was made with the power disconnected and propeller free to turn on the "Van Dyke 2." Figure 19 shows the torque and pounds pull plotted against the revolutions squared. Figure 20 shows a composite curve of all tests.

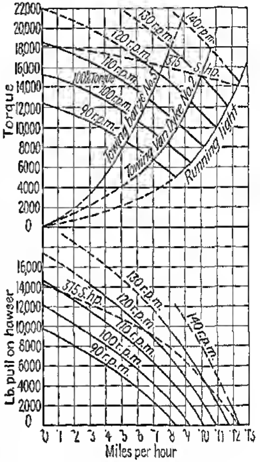

Fig. 20.—Torque, speed, and towing force curves of "Van Dyke 1."

Ships for Special Service. In this classification may be included all types of ships which because of their duty require special maneuvering qualities or ships that can use the main power plant for other purposes than propulsion. Cutters and salvage boats which may be called upon to operate near reefs or which may be pressed into towing service are especially benefited by diesel-electric drive. In installations using two or more main generating units, a switching arrangement is provided whereby a given generator can be disconnected from the propulsive-power loop while underway and diverted to other purposes.

Double-ended ferryboats offer an excellent field for diesel-electric drive as the motor driving the forward propeller may be either electrically dis-

soon as power is developed in this winding, a reaction torque is developed which causes the shaft element to start to revolve in the same direction as the engine element. (This reaction torque is also present in the conventional generator, but the armature cannot turn because it is held stationary by its supports.) The power that is being generated is fed directly into the winding on the outer periphery of the shaft element and, since this is the armature of a synchronous motor, an additional torque is developed to accelerate the shaft element. During this acceleration the field winding of the stationary element is short-circuited through an external resistance. When the shaft element is revolving at close to the synchronous speed of the drive, excitation is applied to the stationary field and the shaft element is pulled into synchronism. Since the engine element continues to run at a higher speed than the shaft element as determined by the speed ratio, there is power developed in the generator winding to operate the motor side of the drive. After the drive has been synchronized, the engine speed may be adjusted to any speed from idling to full load, and the speed of the shaft element will be varied in the same ratio.

In shutting down the Bowes drive, excitation is removed from both the engine element and the stationary element. This deenergizes the drive. If a reversal is required, the drive is deenergized, the engine brought to a standstill, reversed, and brought up to idling speed in the reversed direction. The excitation is then applied to the drive as before.

The Bowes drive is ventilated by means of an external-motor-driven fan arranged to force air into one end of the drive. This air discharges through openings in the end bell on the other side of the drive.

If desired, leads from the generator winding on the shaft element can be brought out to collector rings and a small amount of auxiliary power provided when the unit is running. It is also possible to lock the driven shaft with a brake, open the connections between the two shaft element windings and, by running the engine at the proper speed, generate power for other uses.

Control. The control for the Bowes drive consists of apparatus properly to apply excitation to the field windings in the correct sequence and also to protect the drive. The required relays, contacts, circuit breakers, field discharge, and starting resistors are supplied.

Excitation for the Bowes drive may be supplied from a constant-potential d-c generator driven by the engine or from an auxiliary power supply.

Maintenance. The Bowes drive requires that maintenance which is usually required for proper protection of the conventional a-c motor and generator. Repairs may be made when necessary in the same manner as those required by the conventional synchronous motor or generator.

In cases of emergency it is possible to bolt the engine and shaft elements together so that they act as a solid coupling. The driven shaft may then be operated at engine speed, this speed being set so that overloads on the engine do not occur.

connected or operated at a speed corresponding to zero torque when under way. This permits the power to be applied to the after propeller where it is more effective in producing a net thrust.

Design Characteristics. In all problems dealing with power application, a complete understanding of the characteristics of the driven apparatus should be obtained before starting the design of the driver. In the case of ship-propulsion machinery these items are the hull and propeller.

Motors and generators are designed for a normal power output when operating at a given speed without exceeding a definite temperature, and for temporary operation at a given maximum power without dangerous overheating. As the speed of the diesel-engine-driven generator is independent of the propeller speed, the main concern of the designer is the duty cycle of the motor.

As the most extreme conditions prevail in a tugboat, this application will be considered first. Tests have shown that a propeller when operating at 100 percent apparent slip, the condition ensuing at standstill of boat, absorbs full rated power at approximately 75 percent speed. The torque corresponding to this condition is 133 percent and, current being proportional to the torque produced, the motor must necessarily be designed for this condition. As the conditions existing during acceleration of a tow are of a temporary nature, it is necessary to consider the time element involved and the effect that this excessive current will have on the gradual overheating of the motor.

The heaviest towing condition, which is a continuous operation, dictates the design of the motor and may be considered the basic design factor. Speeds above the heavy towing condition are not of great concern if the machine has been adequately designed for the heaviest operating condition. Motors, however, must be designed for operation between definite current and voltage relationships for, if the speed of a shunt motor is suppressed by increasing the field current, the heating of the field may become a factor.

The accompanying table shows the speed, voltage, and current relationships on a typical basis, for a propelling motor designed for a towboat and operating under towing and running-free conditions.

Propeller, rpm		Volts	Amperes
Towing	Running free		
150	200	240	2,000
135	180	216	1,620
120	160	192	1,280
105	140	168	980
90	120	144	720

It will be noted from the table that the motor under the towing condition has the most strenuous duty and produces the same power output at but 75 percent of the speed attained under the light running condition. The towing condition obviously dictates the motor design.

In actual design practice the engineer has three methods at his disposal for meeting the powering requirements of a ship and in designing the motors to give the highest over-all propulsion efficiency: (1) the single-armature type

CONTENTS

of motor, (2) the double-armature motor, and (3) the use of two or more high-speed motors with gearing. Each of the foregoing types should be studied with relation to the weight, dimensional, and first-cost factors. For shallow craft that limit the motor diameter, the geared arrangement often proves to be the best arrangement from the standpoint of space. The double-armature type of motor is also used for similar purposes.

Ships differ with respect to adequate ventilation in the engine and motor room, and this is a subject of primary importance to the designer. If the heat losses of the engines, generators, and motors are allowed to become cumulative, thereby creating high ambient temperatures, the safe output of the electrical apparatus is limited.

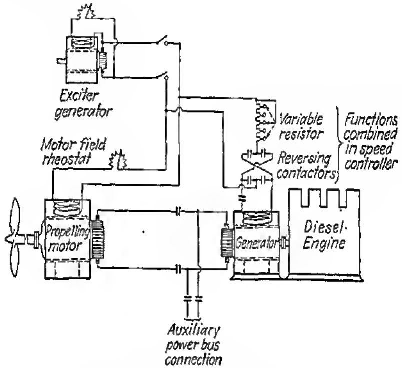

FIG. 21.—Elements of diesel-electric drive system.

In cases where open-type generators and motors are used with integral fans on the rotors, adequate engine-room ventilation must be provided to eliminate the continuous recirculation of the heated air. In installations using a relatively large amount of power, it has been the general practice to enclose the motors and furnish the cooling air by means of separately driven blowers. In the higher power installations the general trend is toward the use of air coolers that use water as the circulating medium for carrying away the heat. This prevents the deposit of dust or grease on the windings and at the same time results in an accurate means of temperature control.

A number of methods are presented to the designer for obtaining the exciting current for the fields of the generators: (1) from an exciter generator driven by the main propulsion unit, (2) from a motor-generator set, and (3) directly from the ship's auxiliary-power bus.

HEATING, VENTILATION, AND AIR CONDITIONING

BY

ABRAHAM THAELER and H. H. HOLLY

GENERAL

Purpose. The purpose of ventilation and heating is the maintenance of satisfactory standards of comfort for the passengers and crew and the establishment of proper atmospheric conditions for protection of the ship's equipment and cargo. Atmospheric conditions through which a ship passes vary more widely and more rapidly than for a fixed location ashore, yet the ship and its contents must be maintained at reasonably constant conditions throughout all weathers.

Until recent years, ventilation and heating were considered as separate problems and were so handled. In modern practice, however, they are treated as two closely allied phases of the same problem. Older ships were heated by a system of direct radiation, generally employing steam-heated radiators; and were ventilated by an entirely separate system of ventilators, ducts, and fans. Recent practice combines the two into a single system, using unheated or cooled air in warm weather and heated air in cold weather.

Marine Conditions. Maintenance of a satisfactory standard of conditions afloat is more difficult than ashore. The wide and rapid temperature fluctuations require an adaptable system; in addition, a marine installation is subjected to many inherent problems. The **watertight integrity** of all watertight decks and bulkheads must be maintained, where ducts and pipes pierce them. The **structural integrity** of strength decks and bulkheads must also be maintained. **Weather openings** are subjected to unusual and severe service. The necessity of recognizing and designing for these conditions is shown by the rules of marine classification societies such as the American Bureau of Shipping and Lloyd's Register of Shipping, which are established to ensure watertight and structural integrity of the weather deck.

Fire hazards must be recognized and reduced to a minimum. The regulations of government agencies such as the U.S. Coast Guard Marine Inspection Service, and agreements such as the rules established by the 1929 International Convention for Safety of Life at Sea and *U.S. Senate Report* 184 must be met. Adequate closures and emergency stops to prevent spread of fire; fireproof or fire-resistant insulation; isolation of inflammable or dangerous materials, etc., should be provided.

Ratproofing of ventilating systems is necessary. Owing to the nature of a ship's structure and the prevalence of rats in many ports, they are a greater problem afloat than ashore. Precautions should be taken to prevent not only establishment of rat homes in ventilating ducts but also migration of rats from one compartment to another by way of the ducts. The U.S. Public Health Service has established regulations dealing with this problem.

Weather conditions vary widely. For vessels designed to operate generally in all parts of the world, air temperatures ranging from 90 to 10 F should be considered for design. For ships in North Atlantic service during the winter, the heating system should be designed for an outside air tempera-

The control panel upon which are mounted the disconnecting switches, speed controller, motor field rheostat, and meters for observation of power output can be made quite simply as the functions are of an elementary nature. As the main power circuits are switched only when the main power circuits are deenergized, the switches are generally operated manually by means of a wheel. A speed controller is generally mounted on the panel, and

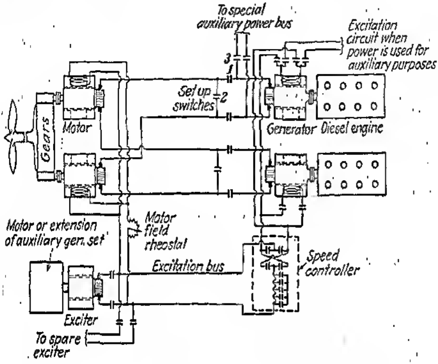

Fig. 22.—Two-generator, two-motor powering system.

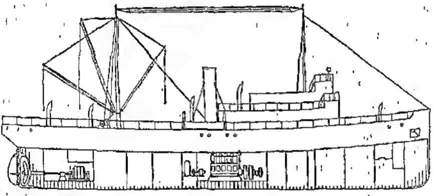

Fig. 23.—Typical method of installation of diesel-electric drive.

a transfer switch supplied for transferring the control to either the bridge or the engine room as desired.

Powering Combinations. It is the general tendency in marine practice to install two diesel-engine-driven generators per propeller shaft, and one or a multiple number of motors per shaft depending upon the power output required. This combination permits a generating unit to be disconnected

ture of 0 F. The humidity of sea air is generally high and, in passing from warm to cool weather, the moisture in the air will condense on cool surfaces and cause "sweat." For this reason, cargo holds should be provided with suitable means for ventilation, to protect the cargo from "sweat damage." Ventilating systems afloat must be able to operate under other adverse conditions, with the ship pitching and rolling; and equipment should operate satisfactorily when tilted as much as 15 deg in any direction and with the usual weather openings closed in rough weather.

Space and weight are invariably limited. This fact must be considered for ducts as well as heaters, fans, and ancillary units. As a result, higher air velocities in the ducts are acceptable, as long as the noise created thereby is not objectionable. The relatively lower ceilings of living quarters require special attention in order to obtain proper diffusion of air. The camber and sheer of ship structure require that ducts follow closely these irregular contours. As living and working quarters are frequently located adjacent to machinery spaces and heat-producing areas, their boundaries require insulation therefrom. **Drainage** of ducts and equipment should take into account the ship's forward motion as well as rolling and pitching. **Corrosion** due to salt air is an important factor, and all materials must be safeguarded. Steel should be protected by galvanizing, painting, or both. The corrosion resistance of aluminum is increased by anodizing, painting, or both.

As the trade routes and operating personnel are frequently changed, **informative labelling** and operating instructions are very important and desirable. Ventilating systems are generally labeled in accordance with the following numbering system.

Designation. Owing to the multiplicity of ventilating systems on many large ships, both merchant and naval, the following method of designation is used for numbering the fans and their attached systems. Each system is designated by a series of numbers: the first indicates the deck immediately below the fan; the second indicates the ship-frame number immediately forward of the fan; the third indicates the athwartship location of the fan relative to other fans at the same deck and frame location. For the third number, odd numbers are used for starboard and even numbers for port fans, starting from the ship's centerline

Deck numbers are as follows:

03. Third deck above weather deck
02. Second deck above weather deck
01. First deck above weather deck
1. Weather deck
2. First deck below weather deck
3. Second deck below weather deck, etc.

Thus, a system numbered 1-47-2 is supplied by a fan on the weather deck; the fan is immediately abaft ship frame 47; the fan is on the port side of the ship. The presence of the third number indicates that more than one fan is at location 1-47.

Special Navy Conditions. Naval ships involve special problems, owing to the following: (1) increased subdivision of compartments; (2) adequate ventilation of ammunition storage spaces, gun turrets, congested living and working quarters, etc.; (3) possible failure of equipment due to combat casualty; (4) fewer permissible weather openings; (5) special restrictions imposed by Navy specifications. The last-named should always be carefully reviewed prior to designing a heating and ventilating system.

from the line under reduced-power conditions, or for overhaul if occasion demands.

Figure 21 shows the elementary, main, and field circuits of a single generator and motor, and Fig. 22 a typical method of electrically connecting two generators and two propelling motors in a series loop. The set-up switches are so arranged that the power may be used for propulsion, cut out of the power loop entirely, or diverted to auxiliary uses. When the generator units are used for special power purposes, the field-excitation circuit is generally connected to the ship's d-c auxiliary-power bus.

The most satisfactory method of driving the exciter generator can be determined only after a study of the auxiliary-power needs and the preferred engine-room arrangement.

Power Limitations When Using Direct Current. Direct-current machinery is used primarily in a low voltage system; consequently the current becomes quite high when large powers are involved. The voltage of the generators generally used is 250. Commutation and the current-carrying capacity of the armature coils become limiting factors in such installations. At the present time the practical field of application lies within a power range of a few hundred horsepower per shaft, up to 2,000 shp when using two generators and two motors per shaft.

DIESEL-ELECTRIC DRIVE USING ALTERNATING CURRENT MACHINERY

Operating Principles and Purpose. In the diesel-electric-drive system of ship propulsion using a-c generators and motors, the operating characteristics are similar in some respects to those obtained with turbine-electric drive. The prime movers operate in one direction of rotation, and the propeller reversals are accomplished by switching the electrical connections between the generator and the motor.

The primary purpose of diesel-electric a-c drive is to adapt the high-speed diesel engine to ships that require powers above those normally obtainable with d-c apparatus. High powers are obtained by paralleling a multiple number of diesel-engine-driven generators on a single power bus. The power that can be applied by this method is limited only by the number of units that can be conveniently located in a ship. Individual generating units can be either connected or disconnected from the power bus as the power demands warrant while the ship is under way.

The speed-reduction ratio between the prime mover and the propeller shaft is a fixed value when the synchronous type of propelling motor is used, and propeller-speed variations are obtained by alternating the speed of the diesel engines.

The torque limitations on the engines when operating at reduced speed are deciding factors in determining the fractional number of units to use for a given power and speed. Figure 24 has been plotted on the assumption that four diesel-engine-driven generators supply the power to an individual propeller shaft at 100 percent propeller revolutions and 100 percent engine torque. It has been further assumed that the minimum safe speed of the engines is 25 percent of rated full speed, and that an engine torque of 50 percent should not be exceeded at this point under continuous operating conditions. Both of these items, however, are subject to the specific recommendations of the engine manufacturer. In this arrangement and assuming that the torque can be safely increased proportionately with the engine speed,

LIVING AND RELATED SPACES

General. In living spaces, the personal comfort of the occupants is the primary consideration. These spaces include public rooms and staterooms for officers and passengers, crew's quarters, and hospital spaces. Also included are spaces in which proper working conditions must be maintained, such as galleys, pantries, bakeries, butcher shop, laundry, radio room, chartroom, wheelhouse, and workshops. This latter group is segregated from the former because it requires special treatment owing to unusual heating and cooling conditions. In all, however, personal comfort is paramount as to both air requirements and distribution.

Miscellaneous spaces such as dry stores, linen lockers, boatswain's stores, CO_2 bottle rooms, deck lockers, gyro rooms, paint and lamp rooms, slop chest, and other infrequently occupied spaces are ventilated for protection of their contents, as well as to ensure safe conditions for personnel who enter the compartment.

Conditions. Table 1 lists desired air changes and temperature conditions for various living and related spaces.

Table 1. Air Changes

approximately 40 percent ship's speed can be obtained with one engine, 60 percent with two engines, and 81 percent with three engines, assuming the shaft horsepower varies as the cube of the speed over the entire operating range. At the higher speeds, the exponent is greater than three.

Paralleling of Alternating-current Generators. The paralleling of an a-c generator is quite a simple process. This type of generator, when connected to the line with its field circuit externally short-circuited, has a similar characteristic to that of an induction motor. This feature permits the second and succeeding diesel-engine-driven generators to be started without

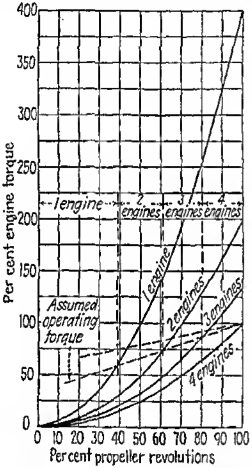

Fig. 24.—Engine torque at varying propeller revolutions.

load, brought up to an approximate speed approaching that of the generator or generators in operation, before being connected across the line. As soon as the generator has attained its slip speed as an induction motor, excitation is applied to the field which brings the generator into synchronism with those in operation. From this point on, the division in load between the generators in operation is controlled by the engine fuel-oil governing system.

Maneuvering Characteristics. During maneuvering operations a propelling motor of the synchronous type is brought up to its slip speed as an induction motor before applying excitation to its field for synchronization. The starting current during this period of operation is several times normal current and, in order to sustain the line voltage, it becomes necessary to

Air changes as given in Table 1 are based on usual minimum air requirements for breathing comfort and on air movement required for removal of odors and body cooling. They do not take into consideration heating and cooling loads and should, therefore, be modified to suit these factors.

Another closely related criterion for air supply to a living space is the minimum air requirement per occupant, accepted values for which are as follows:

	Cfm per Man
Quarters	40–50
Group berthing	30
Mess spaces	25–30

Air volumes based on these requirements will generally exceed those based on air change for a crowded berthing or mess space, while air change, heating load, or cooling load will generally be the determining factor in less densely occupied spaces.

Air supplied to living spaces should be delivered without creating objectionable drafts and as evenly distributed as possible. For private and semiprivate spaces, means for controlling the volume of air delivered should be accessible to the occupant. For public and berthing spaces the individual outlet controls should be accessible to the ship's personnel. For working spaces, air should be supplied at high velocity from terminals with directional adjustment to permit "spot cooling." Both directional and volume control should be accessible to the occupants of the space. For storerooms and similar unoccupied spaces, a continuous air change should be provided with no means of closing off the air, except by means of a fire damper.

Certain spaces that require special treatment in connection with the foregoing air changes are as follows:

Dining and messrooms should have exhaust slightly in excess of supply to prevent spread of odors to adjacent spaces. If the supply is mechanical, the total exhaust should also be mechanical. The excess of exhaust over supply in adjoining galleys or pantries can be utilized for this purpose by means of door louvers or bulkhead grilles. This may take care of the entire exhaust for small messrooms but, for large spaces, additional direct outlets are required to give better distribution and prevent drafts.

Lounges and other public rooms should have exhaust approximately equal to the supply, either direct from the space or from adjoining service rooms and passages. Smoking rooms and bars should have an excess of direct exhaust.

Hospital spaces require special care to assure uniform distribution and freedom from drafts. Individual rooms, or groups of rooms on the same passage, should be individually balanced for supply and exhaust to prevent the spread of odors. Isolation spaces should have a separate mechanical exhaust fan or, if included in a larger system, should have a separate exhaust duct run directly to the exhaust fan inlet.

Galleys, pantries, and other spaces containing heat-producing equipment should have exhaust inlets located directly over such equipment. Canopies should be provided over any equipment from which vapors or fumes are emitted. Local exhausts of this type should always be located on the far side of the equipment, so as to draw heat and fumes away from operating personnel.

Paint and lamp rooms should have but one opening, located in the deckhead or high in the bulkhead and provided with a means of closure.

overexcite the field of the generator. Because of the limited torque characteristics of a diesel engine at slow speed and because above-normal torque is required during periods of acceleration and retardation, it is not feasible to maneuver with only one of a group of engines in operation. In determining the maximum rated motor that can be safely connected to a power line without causing undue line disturbance, the rating of the generating plant must be considered. In normal practice, the generator rating is many times the rating of the motor, whereas in the problem under consideration, the total power of the generating units just equals the power of the motor. Disconnecting power units from the line further decreases the power available.

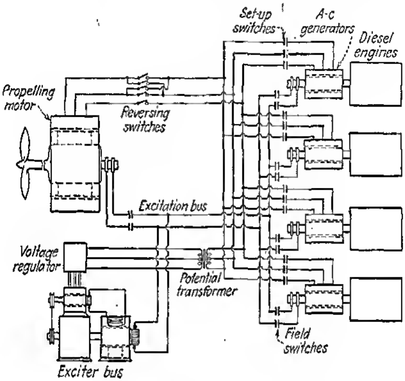

FIG. 25.—Diesel-electric a-c drive with four generating units.

In a turbine-drive ship the power is usually provided by a single large unit in which the torque capacity rapidly increases as the rate of revolutions is forcefully decreased, whereas the opposite is the case when a diesel engine is used.

In reversing a propeller a countertorque must be applied to oppose that produced by the ship's coasting speed which tends to keep the propeller rotating in the forward direction. As the propeller torque is directly reflected on the prime mover in the a-c system of propulsion, the time element involved in getting possession of the propeller will be of longer duration with diesel-electric drive than with turbine-electric drive.

A second consideration in applying diesel-electric drive with a-c generators and motors is the problem of obtaining propeller speeds below those corresponding to the lowest safe speed of the engines. The recommended

CO_2 *bottle room* exhaust should be taken from a point about 6 in. above the deck, with natural supply into the upper part of the space.

Temperatures as shown should be maintained in the living zone of all spaces. Heat, whether by hot blast or convector, should be distributed generally but with particular attention to the cold boundaries—usually outside bulkheads. Insulation should be provided on all boundaries where a high temperature difference exists, to reduce the heating requirements. Attention should be given to the location of exhaust inlets in relation to heating sources, to aid and not hinder the heating operation.

A unit heater serving a space with natural ventilation should, if possible, be located in front of the supply outlet so as to heat the incoming air.

The usual practice of heating **toilets and washrooms** by convector should be modified in cases where there are no adjacent heated spaces from which to draw natural supply. In such cases the outside air supply should be at least tempered. It is then more practical to supply all the heat with a single heater instead of a preheater and convector. In this case the heated supply air should be introduced at low velocity close to the deck, with the exhaust of equal volume taken, as usual, from high in the space. In such cases and provided the size of the space warrants it, it is good practice to use two fans with the systems interconnected. Then, in case one fan fails, the other can supply sufficient air to the entire space to prevent the freezing of piping.

The allowable temperature-rise figures are used to determine the volumes of outside air required for cooling. A definite temperature figure cannot be given since the outside air temperature is the ultimate limit that can be approached by this method of cooling. The amount of outside air introduced into the space should, however, be sufficient to keep the inside air temperature from rising above these limits. The relative amounts of positive exhaust and positive supply required are dependent on the nature of the particular space as regards equipment contained and the degree of occupancy. Inasmuch as air movement is an important factor in body comfort, this factor as well as heat removal should be given due consideration in the design of a system for cooling and, since vessels in most services operate well over half the time under cooling load conditions, its importance should be recognized.

The other method of cooling is by distributing cooled air. This is one function of **air conditioning**. Since this involves a number of other factors, this method will be considered under that heading. It may be said, however, that the temperature to be maintained depends upon the conditions under which the ship operates. In general, 70 to 80 deg effective temperature provides personal comfort in air-conditioned spaces.

Purity and humidity are considered only in living spaces unless liberated fumes, smoke, or gases are present; in which case they must be removed by exhaust. Air supplied to hospital spaces should be filtered, as should also the air supplied to other living spaces if feasible. Space limitations may make the installation of filters impractical. Filters are particularly desirable, however, on vessels in service where people live aboard ship during long stays in port.

Insect screens should always be provided for natural supply and exhaust openings to living spaces, and on mechanical supply intakes to living spaces where filters are not installed.

The problems of oxygen and CO_2 content of air are covered by the air changes recommended and need no further consideration. Warnings should

minimum speeds vary from 25 to 33⅓ percent of normal rated speed among different engine manufacturers.

In many types of ships the minimum propeller speeds obtainable by engine-speed regulation are sufficient. For ships requiring lower speeds, the same must be accomplished electrically. Two methods have been proposed to meet this problem: (1) by means of a small a-c motor attached to the end of the main motor shaft and (2) by operating the main motor on its squirrel-cage starting winding at reduced voltage, thereby increasing its slip.

The type of motor usually recommended for the first solution is the wound-rotor type of induction motor, in which speed control is obtained by means of variable external resistors. Assuming the minimum propeller speed obtainable by engine-speed control to be 25 percent, the corresponding torque is 6.25 percent, and the corresponding horsepower 1.5625 percent. The motor rating must be adequate to provide breakaway torque at the start and be designed for continuous operation at the maximum speed and power for which intended.

The second method entails the incorporation of a special type of generator excitation control with automatic change-over when the speed lever is moved below that corresponding to the lowest safe speed of the engines.

The problems associated with diesel-electric drive which concern the application engineer are (1) a satisfactory method of providing a dynamic braking action on the propeller during maneuvering operations without reflecting this action back to the engines in the form of excessive torque and (2) a satisfactory governing system for parallel operation of the powering units over a wide speed range.

be posted, however, against personnel entering an unoccupied compartment alone without first making sure that the air within is fit for breathing. Portable fan units should be supplied for blowing out tanks and other spaces not provided with installed ventilation.

Humidity control is a phase of air conditioning and will be discussed under that subject. In general, however, 45 to 65 percent relative humidity is the comfort range; the preferred value for a particular case depends on other conditions, both inside and outside.

Methods. Ventilation is the supplying and exhausting of air. Natural ventilation accomplishes this object without the use of a fan. Mechanical ventilation utilizes a fan for propelling the air either directly into or out of a space or through ductwork. A self-evident but often neglected fact is that, in order to accomplish any air change, means for both supply and exhaust must be provided. Since equal mechanical supply and exhaust are seldom provided in a given space, a balancing air quantity must be able to pass into or out of the space under all operating conditions. This may equal the full amount of mechanical air change, and, in such a case, the size and location of the openings are of great importance. Door louvers, undercut doors, or bulkhead openings are the usual means provided for this air movement. Infiltration should be neglected in all shipwork. Thus it is evident that most mechanical systems involve some natural ventilation.

Natural ventilation may be either positive supply, positive exhaust, or neutral, depending on the type of weather opening used. Cowls, porthole wind scoops, and some patented intake heads are generally used for positive supply. Torpedo-type vents, porthole exhausters, and various patented aspirator-type exhausters are used for positive exhaust. Some of the patented exhausters have an advantage over other positive ventilators, in that they do not require trimming into the wind and are practically rain- and sprayproof. Neutral openings—those having no positive action and used for either natural supply or natural exhaust—include mushrooms, goosenecks, and bulkhead openings covered with louvers or wire mesh. The disadvantages of these natural vents, particularly the positive types, are that their performance is dependent on wind conditions; unless of very large size, they handle comparatively small quantities of air against low static pressures; they cannot be operated in bad weather; and their performance cannot be well controlled. A single natural vent head of the positive type will serve a limited number of spaces, since lack of static pressure makes it necessary to keep ductwork to a minimum. When there is more than one outlet on a positive system, regulating dampers should be provided to assure proper distribution, even though it is very difficult to get a close adjustment. It is not practicable to heat natural supply air by duct heaters, owing to the constantly varying volume.

Natural ventilation in living spaces is generally supplemented by bracket fans. Unless such a fan can be located close to a natural vent opening, it will merely circulate the air but, in so doing, will add considerably to body comfort. Porthole fans may also be used for either supply or exhaust. Strictly speaking, they provide mechanical ventilation; but they are generally used in conjunction with natural ventilation, in lieu of an installed mechanical system.

Mechanical ventilation is more expensive to install and operate than natural ventilation. In all other respects, however, it is to be preferred for living-space ventilation, as it is more positive and controllable, requires fewer

BOWES DRIVE

STAFF CONTRIBUTION BASED ON DATA FROM THE ELLIOTT COMPANY

AN ELECTRICAL SPEED-REDUCING TORQUE-MULTIPLYING DEVICE

The Bowes drive is an electrical device for the reduction of speed between high-speed prime movers and driven shafts for mechanical applications where gear and coupling are ordinarily necessary. The immediate application is in ship propulsion where it will be used to reduce the speed of the prime mover, particularly the high-speed diesel engine, to the lower speed required for most efficient operation of the propeller. It may also be used for other applications where speed reducers are required.

Sizes and Types. The Bowes drive covers a range of 300 to 3,000 hp and is built in speed ratios up to 6:1. Any desired speed-reduction ratio up to this value is obtainable, either exactly or very nearly so. The drive is so constructed that the speed ratio once selected is the same for all speeds of the engine and is not adjustable. The drives in operation are of the nonreversing type; *i.e.*, in order to cause a reversal of the driven shaft it is necessary to stop and reverse the drive engine. It can also be built as a reversing drive which will drive the load in either direction without the necessity of reversing the engine.

Description. The following description is for a nonreversing Bowes drive. There are three main elements:

1. An **engine element**, which is solidly bolted to the shaft of the prime mover and which revolves at the same speed as the prime mover. This structure is very similar to the rotating field of a conventional a-c generator. It consists of a spider wheel upon which field poles are mounted. The number of poles is selected so that in conjunction with the other elements of the drive the desired speed ratio is obtained. A field winding is mounted on these poles, and leads from this winding are brought out to collector rings which are mounted on the engine side of this element. Direct current for exciting the field is supplied to this winding through brushes and the collector rings.

2. A **shaft element**, which is solidly attached to the driven shaft. This structure is larger in diameter than the engine element and is mounted concentric with it. This element contains the laminated core and windings usually associated with the armature of an a-c generator. A set of windings on the inner periphery is selected to match the poles on the engine member so that, with the engine running and the generator field poles excited, a-c voltage is generated in this winding. The terminals of this winding are connected directly to the terminals of a second winding which is located on the outside periphery of this member. This winding, since it receives power from the generator winding, becomes the armature of an a-c motor.

3. A **stationary element**, which is mounted concentric with the other two elements and on the outside. It is supported by feet bolted to the supporting foundation. This element consists of a steel ring, inside of which are field poles similar to those on the engine element but of a number selected to produce the desired speed ratio. These poles are also supplied with a field winding and, in conjunction with the winding on the outer periphery of the shaft element, complete a synchronous motor. In addition, a special starting winding is embedded in the pole faces in a manner similar to that

ventilators on the open deck, and is capable, by the use of ductwork, of reaching all parts of the vessel with air taken in through protected inlets located high in the ship. Furthermore, because it is constant and controllable, it can be used for heating and air conditioning.

Mechanical ventilation air is drawn from or discharged to the weather *through louvered openings, mushrooms, or goosenecks* located as high in the ship as possible. Supply intakes should be located so that there is no chance of drawing in gases discharged from the stack, exhaust vent openings, or open skylights. A desirable arrangement for toilet or galley exhausts is to discharge them into the outer casing surrounding the live stack. This removes the ventilator from the open deck and carries the foul air clear of the ship.

Three principal types of fan are all used for mechanical ventilation: propeller, centrifugal, and axial. Each has individual characteristics that recommend it for a particular application. Since these characteristics will be discussed under Equipment (p. 1542), only the fan applications will be mentioned here.

Propeller fans, generally exhaust, may be mounted directly on the bulkhead with no duct work on either side of the fan. Wire mesh should be installed over the bulkhead opening. If the fan is within a man's reach, a mesh guard should be installed on the motor side as well. The cover over the bulkhead opening serves as a fire closure for such systems. If ductwork is connected to the intake side of the fan, easy access must be provided for motor servicing and repair. Ductwork should be kept to a minimum and carefully designed, since the performance of a propeller fan is adversely affected by resistance to the air flow.

Centrifugal fans almost invariably are fitted with ducts connected to both intake and outlet. Large units are generally located in fan rooms, owing to the large amount of deck space they require. Small centrifugal fans may, however, be bulkhead or deckhead mounted in working or even living spaces.

Axial fans are generally located close to their weather opening, either in a fan room or on the open deck. Being of large capacity and with a relatively higher noise level, there should be a reasonable distance between a fan and the first outlet of the system. Their use for living spaces is principally on systems requiring large air volume at fairly high static pressures.

Mechanical supply ventilation to living spaces is generally handled by large systems serving a number of rooms. The systems vary in size from a small fan serving isolated compartments to a group of fans handling large sections of quarters. The arrangement of the vessel must, of course, determine the size of system to be used, but fans of from 5,000 to 8,000 cfm capacity and serving 20 to 40 outlets are commonly used. The upper limit is generally determined by the space limitations of the fan room and the size of duct that may be run. Wherever possible, main ducts should be run in passageways, with branches running outboard between transverse deck beams to the individual spaces. This gives a maximum of headroom below the ducts. Steel structure, piping, and wireways are the principal interferences to be avoided in such a layout. Each main branch should be provided with a splitter damper, and each individual branch with a splitter, regulating damper, or other type of volume control, so that the air delivery from each outlet may be controlled. Each outlet should have, in addition, a shutoff damper. Diffusers and wall registers are most commonly used as

SIDE (say a, Fig. 7). The third angle is known, since $A + B + C = 180°$. To find the remaining sides, use $b = \dfrac{a \sin B}{\sin A}$, $c = \dfrac{a \sin C}{\sin A}$. Or, drop a perpendicular from either B or C on the opposite side, and solve by right triangles.

FIG. 7.

Check: $c \cos B + b \cos C = a$.

CASE 2. GIVEN TWO SIDES (say a and b), AND THE INCLUDED ANGLE (C); and suppose $a > b$. Fig. 8.

First Method: Find c from $c^2 = a^2 + b^2 - 2ab \cos C$ [or $c^2 = (a - b)^2 + 2ab \text{ vers } C$]; then find the smaller angle, B, from $\sin B = (b/c) \sin C$; and finally, find A from $A = 180° - (B + C)$. Check: $a \cos B + b \cos A = c$.

Second Method: Find $\frac{1}{2}(A - B)$ from the law of tangents:

$$\tan \tfrac{1}{2}(A - B) = [(a - b)/(a + b)] \cot \tfrac{1}{2}C,$$

and $\frac{1}{2}(A + B)$ from $\frac{1}{2}(A + B) = 90° - C/2$; hence $A = \frac{1}{2}(A + B) + \frac{1}{2}(A - B)$ and $B = \frac{1}{2}(A + B) - \frac{1}{2}(A - B)$. Then find c from $c = a \sin C/\sin A$ or $c = b \sin C/\sin B$. Check: $a \cos B + b \cos A = c$.

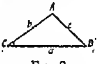

FIG. 8.

Third Method: Drop a perpendicular from A to the opposite side, and solve by right triangles.

CASE 3. GIVEN THE THREE SIDES (provided the largest is less than the sum of the other two), Fig. 9.

First Method: Find the largest angle A (which may be acute or obtuse) from $\cos A = (b^2 + c^2 - a^2)/2bc$ [or $\text{vers } A = [a^2 - (b - c)^2]/2bc$] and then find B and C (which will always be acute) from $\sin B = b \sin A/a$ and $\sin C = c \sin A/a$. Check: $A + B + C = 180°$.

Second Method: Find A, B, and C from $\tan \frac{1}{2}A = r/(s - a)$, $\tan \frac{1}{2}B = r/(s - b)$, $\tan \frac{1}{2}C = r/(s - c)$, where $s = \frac{1}{2}(a + b + c)$, and $r = \sqrt{(s - a)(s - b)(s - c)/s}$. Check: $A + B + C = 180°$.

Third Method: If only one angle, say A, is required, use

$$\sin \tfrac{1}{2}A = \sqrt{(s - b)(s - c)/bc} \quad \text{or}$$

$$\cos \tfrac{1}{2}A = \sqrt{s(s - a)/bc},$$

according as $\frac{1}{2}A$ is nearer 0° or nearer 90°.

FIG. 9.

CASE 4. GIVEN TWO SIDES (say b and c) AND THE ANGLE OPPOSITE ONE OF THEM (B). This is the "ambiguous case" in which there may be two solutions, or one, or none (see Fig. 10).

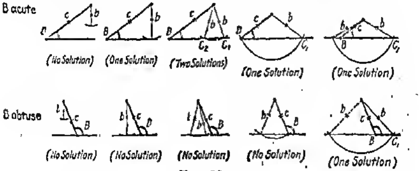

FIG. 10.

First, try to find C from $\sin C = c \sin B/b$. If $\sin C > 1$, there is no solution. If $\sin C = 1$, $C = 90°$ and the triangle is a right triangle. If $\sin C < 1$, this determines two angles C, namely, an acute angle C_1, and an obtuse angle $C_2 = 180° - C_1$. Then C_2 will yield a solution when and only when

$C_1 + B < 180°$ (see Case 1); and similarly C_2 will yield a solution when and only when $C_2 + B < 180°$ (see Case 1).

Other Properties of Triangles. (See also p. 99 and p. 105.)

Area $= \frac{1}{2}ab \sin C = \sqrt{s(s-a)(s-b)(s-c)} = rs$, where $s = \frac{1}{2}(a+b+c)$, and r = radius of inscribed circle $= \sqrt{(s-a)(s-b)(s-c)/s}$.

Radius of circumscribed circle $= R$, where

$$2R = a/\sin A = b/\sin B = c/\sin C;\ r = 4R \sin\frac{A}{2}\sin\frac{B}{2}\sin\frac{C}{2} = \frac{abc}{4Rs}.$$

The length of the bisector of the angle C is

$$z = \frac{2\sqrt{abs(s-c)}}{a+b} = \frac{\sqrt{ab[(a+b)^2 - c^2]}}{a+b}.$$

The median from C to the middle point of c is $m = \frac{1}{2}\sqrt{2(a^2+b^2) - c^2}$.

SOLUTION OF SPHERICAL TRIANGLES

For the occasional solution of a spherical triangle the following formulas will be sufficient. For a detailed discussion, see any text-book on spherical trigonometry.

Let a, b, c be the sides of the spherical triangle, that is, portions of arcs of great circles of the sphere; and let A, B, C be the angles of the triangle, that is, the angles made by tangents drawn to the sides at their points of intersection on the sphere. The sum of the angles will always be greater than two right angles, and may be nearly six right angles. The angle $E = A + B + C - 180°$ is called the **spherical excess** of the triangle. (See also p. 100.)

$$\frac{\sin a}{\sin A} = \frac{\sin b}{\sin B};\quad \frac{\sin b}{\sin B} = \frac{\sin c}{\sin C};\quad \frac{\sin c}{\sin C} = \frac{\sin a}{\sin A}.$$

$$\cos a = \cos b \cos c + \sin b \sin c \cos A,$$

with similar formulæ for $\cos b$ and $\cos c$.

$$\cos A = -\cos B \cos C + \sin B \sin C \cos a,$$

with similar formulæ for $\cos B$ and $\cos C$. Other formulas are:

$$\sin a \cos B = \cos b \sin c - \sin b \cos c \cos A, \text{ etc.};$$

$$\sin A \cos b = \cos B \sin C + \sin B \cos C \cos a, \text{ etc.}$$

If $s = \frac{1}{2}(a + b + c)$ and $S = \frac{1}{2}(A + B + C)$; and if

$$\tan r = \sqrt{\sin (s-a) \sin (s-b) \sin (s-c)/\sin s}, \text{ and}$$

$$\tan R = \sqrt{(-\cos S)/[\cos (S-A) \cos (S-B) \cos (S-C)]}; \text{ then}$$

$$\tan \tfrac{1}{2}A = (\tan r)/\sin (s-a), \text{ and } \tan \tfrac{1}{2}a = \tan R \cos (S-A),$$

with similar formulæ for $\tan \frac{1}{2}B$, $\tan \frac{1}{2}C$, and for $\tan \frac{1}{2}b$, $\tan \frac{1}{2}c$. (Here r and R are the radii, on the spherical surface, of the inscribed and circumscribed circles, respectively.) If $E = A + B + C - 180°$, $\tan \frac{1}{4}E = \sqrt{\tan \frac{1}{2}s \tan \frac{1}{2}(s-a) \tan \frac{1}{2}(s-b) \tan \frac{1}{2}(s-c)}$. If E is small, then approximately, $\sin E = F/K^2$, where K = radius of sphere, and F = area of triangle, regarded as a plane triangle. In any case,

$$\frac{\text{The area of a spherical triangle}}{\text{area of a great circle}} = \frac{\text{spherical excess}}{180°}.$$

In the special case of a right spherical triangle, in which $C = 90°$,
$\cos c = \cos a \cos b = \cot A \cot B$; $\cos a = \cos A/\sin B$; $\cos b = \cos B/\sin A$; $\sin A = \sin a/\sin c$; $\cos A = \tan b/\tan c$; $\tan A = \tan a/\sin b$.

terminals in living spaces. The **punkah louver**, a high-velocity outlet with both directional and volume control, should also be mentioned since it is widely used on foreign vessels and on some American ships. Registers are generally mounted in a cut in the passage bulkhead at the end of a short branch duct, blowing across the space just below ceiling height. If the duct is within a room, the branch (which should be not less than 6 in. long) can be taken off the side, and the register mounted in the vertical ceiling furred in around the duct. A register, particularly when delivering heated or conditioned air, should blow toward an exposed bulkhead and should be designed with sufficient "throw" and dispersion to cover this area. The passage bulkhead location for a register has an additional advantage in the fact that, with mechanical supply ventilation, the exhaust is frequently through a louver set low in the passage door, thus giving the air a full circuit of the room.

Diffusers are mounted either in the ceiling or in the underside of a duct. They should be connected to the duct by a collar at least equal in length to the neck diameter of the diffuser, to prevent too much air discharge on the far side of the terminal. Some diffuser manufacturers supply adjustable grids for this purpose, but the collar is to be preferred for shipwork. It is nevertheless safe practice to have the duct serving a diffuser run toward the exposed side of the room so that any overbalance of air on the far side of the diffuser will discharge toward the point of principal heating and cooling load. The diffuser should be as centrally located as possible so as to reach all parts of the space ventilated. Even when using a combination diffuser and lighting fixture, the location should be dictated essentially by ventilation considerations. Lining up with paneling or light fixtures is desirable for appearance, but such considerations should not jeopardize the ventilation. Where drop ceilings are installed, dampers may be either part of the diffuser or a duct damper with remote control. The punkah may be either bulkhead or ceiling mounted.

Mechanical exhaust may be accomplished either by small individual fans generally located in or adjacent to the space served or by a large fan with ductwork. The latter is the preferred arrangement. Food-handling spaces should be ventilated by a separate system. An exception may be made for a small isolated food space, in which case a separate duct should be run to the fan intake. Toilet systems also should be kept separate, although lockers and other miscellaneous spaces may be incorporated. Exhaust systems are usually smaller than living space supply systems, owing to the fact that exhaust is generally drawn from small widely separated spaces. Ducts are run similar to supply ducts. Outlets should draw from the top of the space, with the exception of those located in spaces where heavy gases such as CO_2 or gasoline may be emitted. Splitter or regulating dampers should be provided for every outlet and main branch. Openings with ½-in. wire-mesh screens are generally used for exhaust. Louvers or commercial grilles should, however, be employed in dining rooms, lounges, and other spaces where appearance is a consideration. Exhaust openings should be located as close as possible to a heat source and at sufficient distance from the supply so as not to short-circuit the air. As in the case of supply, spaces having an excess of exhaust should have door louvers, undercut doors, or bulkhead openings to permit passage of air. Shutoff dampers need not be provided for exhaust terminals, except those whose operation can directly affect the heating of the space in which they are located, such as hospital, radio room, or lounge.

To solve for inlet air temperature, transpose the formula as follows:

$$t_i - 70° = \frac{4141 \text{ Btu}}{1.08 \times 224 \text{ cfm}} = 17 \text{ F}$$

$$\text{Inlet air temperature} = 70 + 17 = 87 \text{ F}$$

The **zone system of hot-blast heating** requires balancing temperature and air volume as illustrated by the following example based on 8 spaces on one reheater:

Example.

1	2	3	4	5	6	7	8	9	10
Room	Cubic	Summer air change	Room, deg F	Btu loss	Est winter air, 65%	Cfm est for 92.6°	Final winter cfm	Final summer cfm	Final air change
A	1,120	5	70°	4,141	146	170	170	260	4.3
B	980	5	70°	2,010	128	112	128	195	5.0
C	980	5	70°	3,055	128	126	126	195	5.0
D	806	5	70°	2,740	105	113	113	175	4.6
E	1,040	5	70°	3,390	135	140	140	215	4.0
F	1,330	5	70°	3,425	173	141	173	270	4.9
G	1,150	5	70°	3,940	150	162	162	250	4.6
H	1,020	4	75°	3,980	166	211	211	325	3.2
Totals......................				27,481	1,131	...	1,223	1,885	

A preliminary inlet air temperature is figured from the above totals (item *H* included as 70 F).

$$t_d = \frac{27{,}481}{1.08 \times 1{,}131} = 22.5 \text{ F}$$

$$t_i = t_r + t_d = 92.5 \text{ F}$$

Using 17.5 F as t_d for item *H* and 22.5 F as t_d for all other items, the cfm for each space is calculated by the same formula and recorded in column 7.

Since four of the eight items in column 7 are reasonably close for the temperature chosen, and two are slightly high, the cfm of items *B* and *F* will be increased to give the final values shown in columns 8, 9, and 10.

The heater for such a system will be as follows: Preheater 0 to 60 F temperature range.

$$\text{Btu} = 1.08 \times 1{,}223 \text{ cfm} \times 60 \text{ F} = 79{,}000 \text{ Btu}$$

Pounds of 35 lb steam required $= \frac{79{,}000}{924} = 86$ lb condensate per hr. Reheater 60 to 92.5 F temperature range.

$$\text{Btu} = \frac{60 \times 1{,}223 \text{ cfm} \times 32.5 \text{ F}}{55.6} = 43{,}000 \text{ Btu}$$

Pounds of 35 lb steam required $= \frac{43{,}000}{924} = 47$ lb condensate per hr.

Mechanical supply and exhaust is the generally accepted standard arrangement for living spaces. In such an arrangement the two should be balanced for any enclosed section of the ship. The smaller the group of spaces that can be balanced among themselves the better, for this cuts down the movement of large air volumes and the consequent danger of unpleasant drafts. It also ensures better distribution of the exhaust, since the spaces affected will be more equally distant from the exhaust and, therefore, more equally benefited by it. The unit may be a deck, part of a deck, or a vertical section through several decks.

It can be seen from Table 1 that the spaces having excess supply predominate in both number and size, the excess air flowing into the passages. Sometimes this extra supply air can be balanced by increasing the volume of exhaust from adjacent toilets, pantries, etc., above the specified air change. It is generally necessary, however, to provide a direct exhaust from the passage equal in volume to the excess supply. This may be by means of a separate system, usually a propeller fan, discharging directly to the weather or into the machinery casing, or by means of an outlet from an existing system. If the supply system is run at reduced capacity for winter operation, the exhaust should likewise be reduced to maintain the balance. This can be done either by reducing the speed of the exhaust fans (this should not be done with a propeller fan) or by shutting down some of the passage exhaust fans. If the fan is run at reduced speed, it is advisable to close some of the passage and other less important outlets so as to maintain the higher air change in toilets or heat-producing spaces. A slight excess of supply is desirable to prevent infiltration.

Heating on shipboard is generally accomplished by one of three methods: direct radiation, hot blast, or unit heater. Steam is by far the most widely used heating medium for shipwork, being generally available and easily handled. Hot-water heating is capable of closer control where small quantities of heat are involved, but it requires a special hot-water generator, as well as larger, and therefore heavier, heaters and piping. Electricity for heating is more easily handled and controlled than either steam or hot water but is too valuable a commodity on shipboard for general heating use. Its principal application at present is for heating isolated spaces which would otherwise require a special steam line.

Steam for heating is taken through a reducing valve from an auxiliary steam line or, on motor vessels, from the waste-heat boiler. Gage pressures ranging from 5 to 50 lb at the heater are used, 30 or 35 lb being the most widely accepted. A two-pipe system is used, with returns run to an atmospheric drain tank from which it is pumped to the deaerating heater and back into the system. All parts of the system must be pitched to drain under normal conditions of trim, drainage forward or aft being better than transverse.

The purpose of providing heat is to maintain a predetermined temperature within a space for the personal comfort of the occupants or the protection of equipment. The heat supplied must be sufficient to replace that lost by transmission through the boundaries of the spaces and to raise the temperature of incoming air to that being maintained in the space. Wherever there is a temperature difference between the air on the two sides of a partition, there is a flow of heat from the warmer to the colder side, the rate of flow depending on the conductivity of the material or materials making up the partition. For bare steel this figure is very high. It is, therefore, necessary to insulate exposed steel boundaries if the amount of heat to be supplied is to be kept

Cooling calculations to determine the quantity of outside air required for cooling to a 10 deg temperature rise can be illustrated by further reference to room *A* in Fig. 2. Assume the heat load in the room to be as follows:

Electrical equipment 1 kw input × 3413	3413
4 lights at 50 watts each = ⅕ kw × 3413	683
2 men at 200 Btu each	400
Solar heat gain (calculated above)	965
Total heat load in Btu	5461

$$\text{Required cfm} = \frac{5461 \text{ Btu}}{1.08 \times 10 \text{ F}} = 506 \text{ cfm}$$

This amount of air would be provided as mechanical exhaust, the excess over mechanical supply (506 − 260 or 246 cfm) being taken in through door louvers or bulkhead opening. If properly located over the main heat source, this amount of exhaust will undoubtedly limit the temperature rise to less than the calculated 10 deg.

Special Features. *Galley pantry and bakery* ventilation is primarily a cooling problem, although, if tempered air is not supplied, some radiation should be provided for an exposed space to keep equipment from freezing when not in use. Air should be supplied from directional terminals located at the working stations preferably about midway between heat-producing areas. Exhaust should be taken from as high as possible over all heat-producing equipment, a wire-mesh covered opening on either the top or bottom of the duct being customary. An intake velocity of about 750 fpm based on gross area of opening should be used.

Canopies should be installed over all equipment emitting large amounts of heat, steam, smoke, or odors. These include ranges, friers, steam kettles, baking or roasting ovens, griddles, dishwashers, etc. A simple and effective canopy consists of a braced sheet-metal curtain plate extending from the deckhead to a point about 6 ft 6 in. from the deck. Around steam kettles, a small gutter to catch condensation should be provided on the inside of the curtain plate. Piping, wireways, etc., should be kept out of the canopy. If this is not possible, a full hood should be built under all obstructions that might collect dirt. From 50 to 75 percent of the galley exhaust should be taken from the canopies, the balance being from over sinks, garbage grinders, etc., or from points necessary for good distribution. Grease filters and a fusible-link fire damper should be installed in the canopies over ranges, friers, and large griddles. Exhaust from a galley should average about 60 cfm per kw input for electrical equipment and about 12 cfm per gal steam-kettle capacity, and figuring approximately 66 percent usage factor for the galley as a whole.

Laundries and tailor shops should be treated in a manner similar to galleys, but canopies are seldom required.

Wheelhouse radiation calculations should include about 25 percent excess to take care of possible open windows.

The **construction** of living-space ventilation systems differs from other systems in a few features owing to the special conditions encountered.

The **magnetic circle,** *i.e.*, all space within 6 ft of a magnetic compass, should be kept clear of ductwork. Any equipment within this area should be of nonferrous material.

Cuts for ducts passing through joiner bulkheads and ceilings should be slightly oversized and finished with a collar. A flanged connection is unnecessary.

within reasonable limits and if the space is to be heated uniformly. Heat supply and insulation of living spaces are parts of the same problem, and the two should be worked out together to determine the most practical combination. The amount of outside air introduced during the heating season should be kept to the minimum ventilation requirements, to keep down the steam load. Since steam is a valuable commodity on shipboard, any heating system should be designed to keep its consumption to a minimum.

Direct radiation denotes heating by radiator, pipe coil, convector, or panel. Cast-iron radiators and bare pipe coils have largely been supplanted by the more efficient convector, although pipes hung on an exposed bulkhead are still used in places such as dry stores when a little heat is needed to prevent freezing. For a given heating area, convectors are considerably smaller and lighter than cast-iron radiators and, therefore, are preferred for most applications. They are best installed on a bulkhead, close to the heating load, with the bottom 8 to 12 in. above the deck. A cutoff valve should be provided in the supply, with a thermostatic steam trap and cutoff valve in the drain line. Most direct radiation systems are manually controlled.

Radiant or panel heating is mentioned here only as a principle that may play a part in future ship heating. The human body experiences the feeling of cold owing to loss of heat from it by radiation. The usual heating methods raise the temperature of the surrounding air and thus cut down to a comfortable point the heat loss from the body. In radiant heating, however, the surrounding surfaces are heated so that heat radiation from them cuts down the radiation heat loss from the body and thus creates a comfortable condition. This is accomplished by heating coils set inside the structure of the room boundaries. Since few living spaces on a ship have more than one or two exposed boundaries and since the ceiled-in air space between structural frames could be easily adapted for heating panels, radiant heating would seem well suited for shipwork. For any given application, however, its feasibility should be determined by weighing the possible saving in heat against the extra weight of piping that panel heating would entail.

Hot-blast heating is a combination of heating and mechanical ventilation. Under this system the heat required to maintain a specified temperature is supplied in the ventilation air by heaters installed in the ductwork. Its principal advantages are that the introduction of heated air permits a higher winter ventilation air change than is otherwise possible; it requires far less steam piping than does direct radiation; it takes up no cabin space; and it can be controlled automatically.

With hot-blast heating, the fan speed should be reduced during the winter heating period to save heat required to raise the temperature of the full amount of outside air. Between 60 and 75 percent of the total summer capacity gives a satisfactory air change and a reasonable entering air temperature for most applications. Main ducts carrying heated air should be insulated and kept as short as possible, to maintain the air temperature to the most remote outlet. Heated air ducts within the space served need not be insulated. Although some recirculation can be used with this system, it has not been widely used, owing to the extra ductwork it would require. Steam lines for blast heaters should have a stop valve in the supply, with a cutoff valve and float-operated thermostatic or inverted bucket trap on the drain.

There are several hot-blast heating arrangements in common use. The simplest is the central system, in which all the air supplied by a given fan is

Owing to limited deck heights and dropped ceilings, ducts in living spaces are generally of flat rectangular cross section. The ratio of width to depth should be kept below 2:1 where possible. If it is necessary to exceed 4:1, a dividing diaphragm should be inserted to give stiffness as well as to aid the air flow.

Insulation is mentioned here only in its relation to ventilation. The insulation of outside boundaries against heat gain and loss should be balanced against the heating and ventilation to determine the optimum amount of each. Sketches of the common types of outside boundaries—bulkhead, shell, or deck—are shown with both welded and riveted stiffening indicated.

Usual insulating materials for boundaries of living spaces are rock-wool or glass-wool insulation with marine-board sheathing. Sheet-metal sheathing instead of marine board is used in washrooms, storerooms, etc. Cork paint is frequently used in washrooms; but this is primarily to stop sweating, and its insulating value can be neglected.

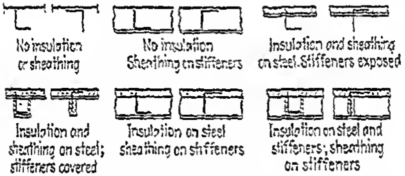

FIG. 3.—Typical outside boundaries.

Ducts carrying cooling air should be insulated wherever they pass through the machinery casing or other hot spaces. Ducts, heaters, and fans carrying heated air should be insulated except within the space they serve. An exception is a single fan and heater system in a fan room, used as an intake plenum, in which case any heat dissipated is drawn back into the system. Insulation should be blocks of mineral wool, or its equal, generally 1 in. thick, securely fastened by adhesive and metal bands, spaced not over 18 in. apart. Where ducts are exposed, a canvas cover should be sewed on over lagging. Insulation over access holes should be portable.

Noise problems are frequently very complex and so belong to the sound engineer and not to the ventilation designer. There are, however, certain rules of good design that can reduce noise in a ventilation system.

There is no general rule as to noise limits, since each location has its own desirable sound level. Although the general sound level on shipboard is comparatively high, allowing more liberty in ventilation noise, ship construction materials are better sound conductors than most building materials. As in shore work, however, noise is carried in the air stream, through the ship structure, or can be caused by the air in the terminal. Also, as in shore work, there are two remedies for excessive ventilation noises: elimination of the source and cutting down the transmission of existing noise.

The fan is the principal source of ventilation noise. The first step in preventing noise should therefore be the selection of the proper fan for a particular application. A rating of 85 decibels is acceptable for a machinery

heated to the predetermined temperature necessary to maintain the specified temperature in the space or spaces served. This may be accomplished by a single heater covering the total range or by a preheater to temper the cold outside air, and a reheater to raise the air to the required temperature. The two-heater arrangement is capable of closer control. Either room thermostats or compensated duct thermostats may be used for control. If only one heater is used, the control should be such that, when the desired temperature is reached in the space, the heater can deliver tempered air only. Such a system has the advantage of simplicity but can be used only for a group of spaces with comparable heat loss and specified air change and with outlets within a fairly limited area.

The most widely used hot-blast heating arrangement is the zone system which differs from the central system in that it consists of one preheater and several reheaters, each serving a heating zone. The thermostat-controlled preheater on the intake side of the fan delivers tempered air at a constant temperature, generally 50 to 60 F. The latter is desirable if there are spaces to receive tempered air from the system. The duct supplying such spaces is taken off directly after the fan. Other main branches each contain a reheater controlled by either room thermostat or compensated duct thermostat. Each reheater is sized to provide air at the calculated temperature required to maintain the specified condition in the spaces served. The reheater should be located so that the distance to the most remote outlet is not too great. There are frequently spaces in a given section of the ship, inside rooms for example, which require the same air change as near-by spaces but which have far less heating load. These spaces should receive all tempered air; or have two outlets, one supplying heated air and one tempered air; or should have the air change provided by exhaust with the supply of 70-deg air drawn in from the passage. The choice of method will depend on the conditions in each case. The zone arrangement gives greater flexibility than the central system, since it can serve groups of spaces requiring different entering air temperatures and also deliver tempered air. A typical zone layout is shown in Fig. 16.

The individual system differs from the zone system only in that there are separate reheaters for each individual space, controlled manually or by a room thermostat. Since the heat required from each reheater under this arrangement is small, hot-water or electric heat has advantages over steam. Individual control is the great asset of this system, but its use is not often feasible owing to difficult installation and expense of the piping and numerous heaters.

Another arrangement giving individual control is the dual-duct system by which two ducts, one carrying heated air and one tempered air, are run together into each space, where they meet in a mixing chamber at the terminal. By adjusting the terminal, the room occupant can regulate the temperature of the entering air mixture. The punkah louver is frequently used with this system. The disadvantage of the dual-duct system is the difficulty and expense of installing the two ducts throughout a ship.

Unit heaters are used in workshops and miscellaneous spaces which have no installed mechanical ventilation but which need both heat and air change at times when men are working therein. Being easily located and installed, unit heaters are well suited to take care of these special cases. They are generally steam-heated but can be electric- or hot-water-heated. Steam lines should have a stop valve in the supply and a cutoff valve and float thermostatic or inverted bucket trap preceded by a dirt trap or drain.

space fan but is far too high for a hospital system. Axial fans are in general noisier than centrifugal fans and therefore should not be used where noise is objectionable. Tip speed is a rough index of fan noise and should be kept low if possible. A limit of 8,000 to 10,000 fpm is desirable and should be exceeded only after consideration of the noise problem. Also, care should be taken to see that a large fan is running in its range of greatest efficiency since axial fans and forward-curved-blade centrifugal fans in particular become noisier if run otherwise. In cases such as engine rooms where shutting off several terminals will greatly affect the fan performance, instructions should be given to reduce the fan speed when more than about one-third of the terminals are closed. Also, the air entering a fan should be evenly supplied over the entire inlet, since uneven supply creates an unbalance that increases noise. All fans should be rigidly mounted and the surrounding structure stiffened if necessary so that they cannot vibrate. Canvas connections between centrifugal blowers and ductwork, commonly used in shore work, are not ratproof and cannot be used. Since ratproofing such a connection is not satisfactory, the preferred connection, with no metal-to-metal contact, is by means of a 1-in. rubber gasket with fiber ferrules and washers as shown in Fig. 4.

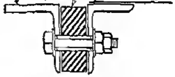

FIG. 4.—Fan connection.

Air noise in terminals can be prevented only by keeping the outlet velocity within proper limits for the type of outlet in question. In ducts, air noise can be prevented by using proper velocities and being sure that the inside surfaces of the ducts are smooth and free from projections and bad fittings.

In regard to noise carried in the air stream, it is popular fallacy that sound does not travel against the air flow. Since sound travels in air at the rate of around 65,000 fpm, the effect of the air velocity—under 3,000 fpm—is negligible. The noise level of a system should be considered not only for the space ventilated but also in the vicinity of the intake, which may be near a navigating station or sleeping space. If the source of the excessive noise cannot be eliminated, the installation of a sound-absorbing material is necessary. If the problem is in an existing installation, the system should be tested with a decibel meter with analyzer, and a sound engineer should be consulted as to the proper treatment, since sounds of different frequencies should be treated in different ways. In designing sound treatment for a new system, it should be remembered that the penetrating whine which comes from a high-speed fan is mostly a high-frequency sound which is best removed by closely spaced sound-insulation units. A general rule for the amount of insulation required is 10 to 15 diameters of duct or its equivalent. Since lining this length of duct is seldom feasible in shipwork, a sound trap is usually more practical and, for equal area, more effective, particularly to minimize high-frequency sound.

The sound-absorbing material should be noninflammable, unaffected by dampness and, if of the mineral-wool type, about 1 in. thick and held in place by wire screen or perforated sheet metal. A practical and effective sound trap can be made by using panels with material exposed on both sides, spaced on about 6 in. centers, extending the width of the trunk, and running parallel to the air stream. If space and the static pressure of the fan permit,

Air conditioning is the process of maintaining, within fixed limits, the temperature, humidity, movement, and quality of air in a space. In its purpose, it differs from straight mechanical ventilation only in the degree of treatment and control, but practically the cooling of air for temperature and humidity control introduces so many new factors that air conditioning must be regarded as a separate subject. In the following, an attempt is made, not to describe the subject thoroughly, but merely to bring out a few points in connection with its use on shipboard.

Complete air conditioning requires a large installation, the cost of which is not justified in most cases on shipboard. There are few large passenger vessels, however, which are not equipped with some form of cooling and humidity control for the public spaces for passengers and crew. How many additional spaces should be conditioned and the extent of the treatment depend on the service for which the vessel is intended. It seems likely, *however, that passenger ships in many services will have at least some* cooling in all staterooms, either for comfort or for its advertising value.

The index of air conditioning is the "effective temperature" or so-called comfort scale. This is an experimentally established scale of comfort which takes into consideration dry- and wet-bulb temperature and air movement. On this basis, different combinations of the three factors can produce the same effective temperature and the same degree of comfort. What exact values should be maintained depends on the outside conditions, since extreme contrasts are unpleasant, even though the inside effective temperature may be well within the comfort range. In other words, no one temperature is the optimum under all conditions. For example, a ship operating in the Caribbean with 95 deg temperature has an air-conditioning plant to give 80 F and 70 to 75 deg effective temperature; a ship in Red Sea trade, where 100 F and 80 percent relative humidity are met, has a plant to give 90 F and about 80 deg effective temperature; one in the Pacific with 90 deg and 75 percent relative humidity has a plant designed for 85 F and 70 to 75 deg effective temperature. Thus, although the effective temperatures generally fall between 70 and 80 deg, the plant must be chosen on the basis of the outside conditions to be encountered.

The required refrigeration can be estimated as follows: From the desired inside temperature, the expected outside temperature, and number of occupants, the heat gain in the space can be calculated (see p. 1523). The amount of outside air to be brought in and the amount of dehumidification having been decided upon (this being affected by the amount of recirculated air), the temperature and total heat of air leaving the cooling surface can be determined (see p. 375). The heat gain in the space, plus the dehumidification, plus the sensible cooling of the outside air to space temperature are the refrigeration required.

The question of purity is not so vital in average shipwork as it is in land work, owing to the relatively high purity of the air encountered by ships in most services. As a consequence and because of the importance of saving space and weight, filters may be used with installations that would warrant an air washer ashore. The proper amounts of oxygen and CO_2 in the space are assured by the constant introduction of about 25 percent of outside air.

Heating is handled by a hot-blast system, similar to straight mechanical supply ventilation; plus provision for raising the humidity as necessary by injection of steam or a water spray into the air stream.

A duct layout for air conditioning is very similar to that used with mechanical supply ventilation and heating, plus a return duct system to pick up and

the trap can be made more effective by zigzagging the panels, using 9- to 12-in. straight sections and sufficient angle to close the direct line of air flow through the trap. Panels should be removable for repairs and should be evenly spaced with their leading and trailing edges formed so as to disturb the air stream as little as possible. Another type of sound trap applicable to weather openings is obtained by lining the intake chamber or mushroom and vanes between the fan and the weather. This arrangement is simpler than the panel type but is less effective, owing to the smaller area of absorbing material.

The **fan room** is the heart of a ventilation system and, as such, its design is important to the operation of the entire unit. Although fan rooms may be of any size and contain any number of fans and other pieces of ventilating equipment, there are general features that should apply to all. They should be located close to the spaces ventilated and thus keep ducts short. The intake should be in as protected and weatherproof a location as possible, to

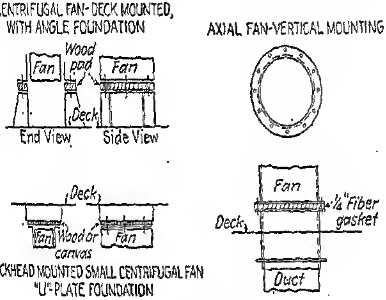

FIG. 5.—Fan foundations.

minimize chance of forced shutdown. In a fan room for living-space supply either the room intake or the fan inlet must have filters or insect screen. A single fan may be direct-connected to the weather opening. In cases of more than one fan of the same type—supply units particularly—the fan room itself is generally used as a plenum chamber. Filters should be connected to the fan inlet but, if space requires that they be connected to the room intake, there should be at least 18 in. between the weather opening and the filters to cut down the chance of water freezing on the filters. Washing and recharging equipment should be located close to filters and provided with permanent drain and water connections. If the room is used as a plenum, the gastight door to the compartment should be kept closed at all times. Preheaters should be mounted on the fan suction, with sufficient space between filters and heaters and between heater and fan intake, to assure good air distribution. Heaters should be firmly supported from either deck or deckhead with ample space allowed for piping connections. Fans should be rigidly mounted on foundations or blocks set on deck, with shafts either vertical or fore and

recirculate about 75 percent of the supply air. The remaining 25 percent must be exhausted by regular means. Ductwork should be insulated. Distribution is a feature of the utmost importance in any air-conditioning system but, with the low ceilings encountered on shipboard, it requires even greater attention. Outlet and intake velocities must be kept low to prevent

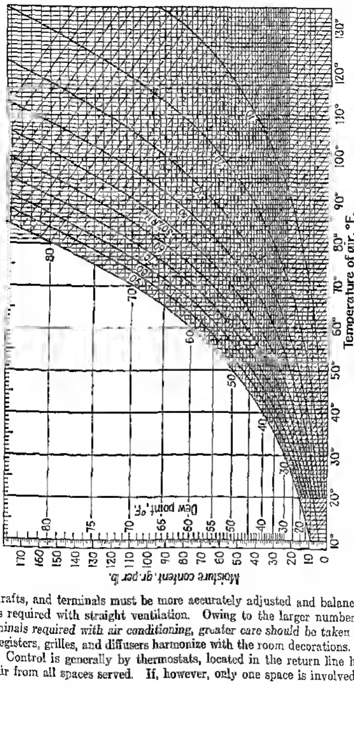

FIG. 1.—Psychrometric chart for determining the dew point and moisture content of air from wet- and dry-bulb readings or from temperature and relative humidity readings (see pp. 376–378).

drafts, and terminals must be more accurately adjusted and balanced than is required with straight ventilation. Owing to the larger number of terminals required with air conditioning, greater care should be taken to have registers, grilles, and diffusers harmonize with the room decorations.

Control is generally by thermostats, located in the return line handling air from all spaces served. If, however, only one space is involved or if a

aft, to reduce wear on bearings. Figure 5 shows some general types of fan foundations. Space must be allowed to permit easy servicing of fans and for the unshipping of the motor if this should be necessary. If it is desirable to isolate the fan for noise reduction, fiber ferrules and washers can be used in addition to the pads shown to prevent metal-to-metal contact.

Axial fans with duct connections on both sides must have a spacer ring above the fan, to permit making up the flange connection to the fan. An axial fan drawing or discharging without ductwork should have a sheet-metal bell to ease the air flow.

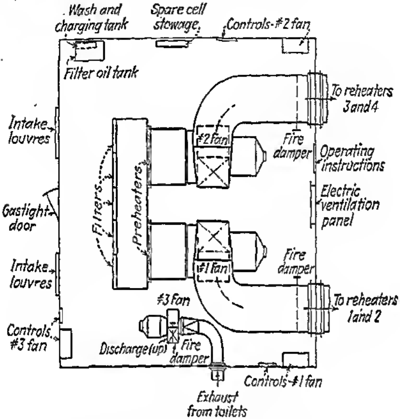

FIG. 6.—Typical fan-room layout.

Electrical controls should be located on a bulkhead close to the fans and out of the intake air stream. Compensating thermostatic bulbs must be located directly in the intake air stream so that they will register true outside air temperature. Reheaters should be located in the fan room if doing so does not make the duct run beyond the heater too long. Reheaters should always be pitched 1 in. for drainage. Fire dampers should be located in fan rooms where they are easily controlled from the one place.

A layout for a fan room containing three living-space centrifugal fans—two supply and one exhaust—is shown in Fig. 6.

MACHINERY SPACES

General. Machinery spaces include those spaces housing boilers, main and auxiliary engines and equipment, emergency generators, steering gear,

particular space requires especially close control, a room thermostat should be used. Automatic humidity controls are available, but more often manual control based on a humidity indicator is provided.

Air-conditioning equipment can be of the regular commercial type, with necessary marine features incorporated to adapt it for marine use. Freon is the most generally accepted refrigerant. Central systems, in which all the equipment is located in a machine room, are preferred. There are also, however, self-contained units in which the fan, compressor, condenser, etc., are in a self-contained cabinet and unit coolers with independent fan and coils. Certain installations, frequently those on conversions, necessitate the use of self-contained units, owing to simplicity of installation. Particularly for vessels that encounter extreme variation in cooling load, it is good practice to provide two compressor units which together have peak-load capacity, and either one of which can handle the average load, with the other as a stand-by. In all such considerations it should be remembered that air conditioning is a luxury and not a vital service, as are ventilation and heating. Economy of installation and operation is therefore of great importance.

Calculations. Heat gain or loss from any space equals the algebraic sum of the heat transferred through its various boundaries.

The heat transmitted through a boundary may be determined as follows:

$$H = A \times U \times t_d$$

where H = total heat transmitted, Btu per hr
A = area of the boundary, sq ft
U = over-all coefficient of heat transfer, Btu/(hr)/(sq ft)/(deg diff)
t_d = difference in temperature between the two sides of the boundary, $= t_1 - t_2$, in deg F

The value of U is determined by the following formula:

$$U = \frac{1}{\dfrac{1}{f_o} + \dfrac{X_1}{K_1} + \dfrac{1}{a} + \dfrac{X_2}{K_2} + \cdots + \dfrac{1}{f_i}}$$

where f_o = outside surface conductance, Btu/(hr)/(sq ft)/(deg F)
f_i = inside surface conductance, Btu/(hr)/(sq ft)/(deg F)
K = conductivity of the material, Btu/(hr)/(sq ft)/(deg F)/(in. thickness)
X = thickness of the material, in.
a = conductance of the air space between the materials, Btu/(hr)/(sq ft)/(deg F)

All of the foregoing are definite values, but they vary somewhat with the temperature at which the heat transfer takes place. Also, the surface conductances vary greatly with the velocity of the air moving over it and whether or not the surface is wetted. Table 2 lists values for typical ship boundaries as generally used for average conditions. These do not necessarily agree with the simple formula, owing to the fin effect of stiffeners and other contingent factors.

cargo-oil pumps, and special electrical equipment such as electrical storage batteries and resistors. Where the equipment is in continual use and is constantly radiating at least sufficient heat to ensure comfortable working conditions, ventilation alone is required; the chief purpose of the ventilating system in these spaces is to supply sufficient fresh air to limit the temperature to a maximum consistent with comfort. Main and auxiliary boiler and engine rooms generally are in this category. Where operation of equipment is intermittent or where the equipment is not giving off sufficient heat to ensure proper conditions, both heating and ventilation may be required. Compartments housing emergency generators and steering gear are typical spaces that should have both ventilation and heating. For spaces housing special electrical equipment such as large storage batteries, which give off objectionable vapors and which must be kept from extremes of heat and cold, both heating and ventilation should be provided. Electrical equipment is adversely affected by very moist air, particularly salt air; and electrical controls and resistors for intermittent-service auxiliaries, such as deck winches and capstans, should be protected from moisture and condensation during inoperative periods by proper heating equipment. When such auxiliaries are in use, the heat radiated therefrom must be removed by ventilation. Emergency generators are frequently located in inside rooms, without direct doors or openings to the weather. Unless proper provision is made for the supply and exhaust of ventilating air to such spaces, satisfactory operation is impossible, as the heat given off by their radiators is very considerable and the cooling medium will soon reach boiling temperature.

Cargo-oil pump rooms on tankers require adequate ventilation to remove explosive, noxious, and toxic vapors emitted by the oil. On tankers carrying light petroleum products such as gasoline or naphtha, the vapor released in cargo pump rooms, particularly in warm weather, is considerable. The vapor, being heavier than air, settles in the bilges and should be removed to reduce the fire hazard and eliminate the toxic effect on the operating crew.

Refrigerating-machinery rooms require, generally, the same consideration as other machinery spaces. Where ammonia is the refrigerant, ventilation should be adequate and positive, as ammonia is toxic and corrosive to copper and cuprous alloys. It has been largely superseded for marine use by the halide refrigerants, of which dichloro-difluoromethane, generally known as Freon, is the most common. Freon is nontoxic and noninflammable, and hence the ventilation of Freon refrigerating rooms is not so critical.

Conditions. Main machinery spaces do not generally require any heating, as the heat radiated from the machinery is sufficient to ensure comfort, even in cold weather. Ventilation, however, is most important, particularly for operation in warm water and weather. All the heat losses in the machinery spaces must be carried away by the ventilating air and, to ensure reasonable comfort for the operators, the temperature rise of the ventilating air should not exceed 30 deg F. A maximum rise of 25 deg F is preferable. With outside air at a temperature of 90 F and an air temperature rise of 25 deg, the temperature of air leaving the space will be 115 deg, which is a maximum desirable for comfort of the operators.

The system should permit regulation of the quantity of ventilating air, otherwise the spaces will be unduly cold in winter weather. If natural ventilation is used, control dampers in the supply ducts should be installed. For mechanical ventilation, speed variation of the fans of at least 25 percent

Table 2. Over-all Heat-transfer Coefficients

(For various types of boundary construction)

Construction	U
Painted steel:	
Inside bulkhead ($K = 300$)	1.00
Outside shell (12-knot wind)	1.10
Outside steel—air space—¼-in. marine board	0.45
Steel:	
2-in. rock wool—sheet-metal facing	0.20
2-in. rock wool—³⁄₁₆-in. marine board	0.19
2-in. rock wool—air space—½-in. marine board	0.15
2-in. cork, painted	0.25
2-in. glass wool—glass cloth	0.19
Steel deck:	
Painted—¾-in. magnesite covering	0.55
12-in. cork (refrigerated spaces)	0.04
Wood deck—steel, painted	0.31
¾-in. marine board bulkhead	0.48
Airport light—14 in. diam (closed)	0.50

In Table 2, the following values of conductivity and conductances were used:

Steel, conductivity	$K = 300$
Marine board, conductivity	$K = 0.86$
Rock wool, conductivity	$K = 0.27$
Cork, conductivity	$K = 0.30$
Glass wool, conductivity	$K = 0.25$
Outside surfaces, film conductance	$f_o = 6.00$
Inside surface, film conductance	$f_i = 1.65$
Air space, over ¾ in. thickness, conductance	$a = 1.10$

Heat-transfer calculations should be based on the extreme outside temperatures, in order to determine the peak heating or cooling load. These vary with the service for which the vessel is intended. The following may, however, be used as designed extreme temperatures, in degrees Fahrenheit, for general cases:

Element	Temperature, deg F	
	Winter	Summer
Outside air	0	85
Sea water	35	85
Hold, unheated	20	85
Deck:		
Wood	0	120
Steel	0	140
Vertical bulkhead, steel	0	120

In determining cooling loads, the heat from human occupants should be based on 200 Btu per man per hour, based on total occupancy; the heat from electric lighting or resistance heat = 3413 Btu per kwhr. In public spaces, the electric-lighting load is about 2 watts per sq ft deck area. These should not be considered as a source of heat when determining the heating load.

is advisable, and the outlet terminals should also have control dampers for further reduction of air supply in cold weather.

Steering engine rooms do not generally have an operator in constant attendance and do not, therefore, require so close temperature regulation. As the heat liberated is generally small, natural ventilation, either by supply or exhaust, is sufficient. However, some degree of heating is advisable, particularly if the steering gear is electric, and may be provided by electric or steam heaters, of either convector, unit heater, or radiator type.

Emergency generator rooms should have sufficient ventilation to ensure adequate cooling air for the air-cooled radiator and for combustion.

Methods. Ventilating systems may be either supply, exhaust, or a combination of supply and exhaust; and the air may be handled by either natural or mechanical means. **Natural ventilation,** by the use of supply and exhaust cowls and their attendant ducts, has been much used in the past and is fairly satisfactory if well laid out, but it requires large ducts to ensure low friction loss. Natural ventilation depends on the velocity of the air relative to the ship for its efficiency, and the supply cowls must be trimmed in the direction of the relative air velocity. Whenever the ship changes course or the wind direction changes, the position of the cowls should be changed accordingly. If there is a following wind, the ventilating effect will be very small and the space excessively hot. The prevalent trend to machinery casings of small area also restricts the possible sectional areas of vent ducts for main machinery spaces. **Mechanical ventilation,** with either supply or exhaust fans or a combination of both, ensures a positive and controllable supply of air for all operating conditions and also permits use of ducts of moderate dimensions. Owing to the larger permissible friction losses, the ducts may be more extensive and a better distribution of air obtained, resulting in a more equable temperature of the spaces.

Mechanical supply ventilation comprises one or more supply fans, taking outside air from fixed intake heads and discharging it through a duct system to the various outlets, properly located to scavenge any hot zones. The heated air rises up the machinery casing and is discharged to the outside through either a skylight or other exhaust opening.

Mechanical exhaust ventilation comprises one or more exhaust fans, collecting heated or vitiated air from various locations through a duct system and discharging it through a suitable exhaust opening to the outside air. The air is naturally supplied to the lower part of the space either through large ducts or down the machinery casing itself. This type of system is not generally used by itself.

Combined mechanical system is a combination of mechanical supply and mechanical exhaust. Exhaust inlets are properly located to withdraw vitiated air from "hot spots" or zones where considerable heat is liberated.

Of the above systems, the mechanical supply system is probably the most efficient and economical for the main machinery spaces. The ability to provide effective distribution of cool air and the utilization of the machinery casing as a natural draft "flue" for the heated air are desirable factors. In steamships, where a large supply of air is required for combustion of fuel in the boilers, the forced-draft fans frequently take their suction from the upper *machinery space, where the air is warm, and draw it down through an air* casing surrounding the stack, thus further assisting in the ventilation.

Frequently a large outer stack is fitted around the live stack, for the sake of ship appearance. If the exhaust ventilating air is permitted to rise to

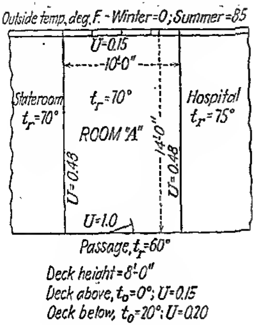

FIG. 2.—Typical space.

Figure 2 represents a typical space, for which the winter heat loss would be calculated as follows:

Boundary	Dimensions	Area, A	Heat-transfer coef U	Temp difference, t_d	Heat transmitted, $H = A \times U \times t_d$
Outboard side....	10' × 8'	80	0.15	(70 − 0) = 70	840
Forward side.....	14' × 8'	112	0.48	(70 − 75) = −5	(−) 369
Inboard side.....	10' × 8'	80	1.0	(70 − 60) = 10	800
Aft side.........	14' × 8'	112	0.48	(70 − 70) = 0	0
Deck over........	14' × 10'	140	0.15	(70 − 0) = 70	1470
Deck under.......	14' × 10'	140	0.20	(70 − 20) = 50	1400
Total heat loss, Btu per hr....					4141

The summer heat gain, based on 10 deg temperature rise (*i.e.*, 95 F in all spaces) and bare steel deck overhead would be calculated as follows:

Boundary	Dimensions	Area, A	Heat-transfer coef U	Temp difference t_d	Heat transmitted $H = A \times U \times t_d$
Outboard side....	10' × 8'	80	0.15	(120 − 95) = 25	300
Other 3 sides....	....	....	....	(95 − 95) = 0	0
Deck over........	14' × 10'	140	0.15	(140 − 95) = 45	915
Deck under.......	14' × 10'	140	0.20	(85 − 95) = −10	(−) 250
Total heat gain, Btu per hr....					965

Cubic volume (always based on empty volume) = 1,120 cu ft.

the top of the outer stack and then discharged through openings around its after perimeter, additional natural-draft "flue effect" will assist the ventilation.

Cargo-oil pump rooms on bulk-oil tankers require special consideration. The explosive and toxic vapors settling in the bilges and lower zones should be effectively removed by an exhaust duct system, extending from the space below the floor plates to outlets located well above the deck. A small steam jet eductor or an exhaust fan, in the duct, induces the upward flow of vapor. Care should be exercised to prevent any spark or flame in this duct. If a motor-driven fan is used, the motor should be located outside of the duct.

Heating of main machinery spaces is not generally required, as the heat radiated is generally sufficient to ensure a livable temperature. However, spaces housing the steering gear, emergency generator, storage batteries, etc., should be provided with some means for heating to protect the equipment from moisture and excessive cold. Where steam lines of suitable pressure are located near by, direct heating, either by steam radiators or by "unit heaters" (fin-tube radiator with a small electric fan blowing across the heating element) is economical. If there is no steam supply near the space, electric resistance heaters are suitable; however, it should be borne in mind that electrical energy is an expensive source of heat, and resistance heaters cannot be economically used to supply a large amount of heat. Storage-battery rooms should have only sufficient heating to prevent freezing; high temperatures will cause excessive evaporation of water from the electrolyte. Electrical resistor rooms or spaces should be heated sufficiently to prevent condensation of moisture from the sea air on the resistors and contactors. Frequently, contactor panels for deck machinery are fitted with a strip or coil of resistance wire at the base, which gives off sufficient warm air to rise across the contactors and keep them dry.

Calculations. For main machinery spaces, the problem is to determine the amount of heat given off by the machinery and equipment, so that adequate air may be supplied to remove this heat with a moderate temperature rise. The heat given off by a well-designed steam plant amounts to approximately $1\frac{1}{2}$ to $2\frac{1}{2}$ percent of the heat content of the fuel burned. To meet this figure, the boilers, steam piping, and auxiliary units must be well insulated, so that the surface temperature of the insulation does not exceed approximately 135 F. This surface temperature likewise will protect the operating personnel from burns.

The heat given up to the air can be determined with good accuracy by calculation. For insulated surfaces such as steam pipes, boiler casings, etc., the heat radiated from the surface may be determined as follows:

$$H_0 = K \times S \times (t_s - t_a)$$

where H_0 = heat radiated, Btu per hr
K = coefficient depending on the type of insulation covering, = 0.35 – 0.50
S = total surface over the insulation, sq ft
t_s = surface temperature of the insulation; should not exceed 135 F
t_a = ambient temperature of surrounding air; about 100 to 110 F

If the air velocity sweeping the surface is high, the heat radiated will be increased considerably. If the velocity of the air is 10 fps, the heat radiated will be approximately three times the value given by the formula above.

Heating requirements by radiation are figured as 240 Btu per sq ft of rating based on steam at 215 F. For other steam temperatures, the value of 240 Btu must be divided by the following factors:

For radiators:

$$C = \left(\frac{215 - 70}{T_s - T_r}\right)^{1.3}$$

For convectors:

$$C = \left(\frac{215 - 65}{T_s - T_i}\right)^{1.5}$$

where T_s = steam temperature, deg F
T_r = room temperature, deg F
T_i = inlet air temperature, deg F (5 deg lower than room temperature)

Example. *By Means of Steam.* Assuming a steam pressure = 50 psi (temperature 298 F, from steam tables), the convector requirements for room *A* (Fig. 2) are as follows:

$$240 \div \left(\frac{215 - 65}{298 - 65}\right)^{1.5} = \frac{240}{0.517} = 464 \text{ Btu per sq ft}$$

$$\frac{4141 \text{ Btu}}{464 \text{ Btu per sq ft}} = 9 \text{ sq ft convector surface to overcome heat loss and to maintain 70 F with 0 deg outside}$$

Steam required would be

$$\frac{\text{Total Btu per hr}}{\text{Latent heat per lb of 50-lb steam}} = \frac{4141}{910} = 4.55 \text{ lb condensate per hr}$$

By Means of Hot Water. Convector requirements for heating with **hot water** are based on a rating of 150 Btu/(sq ft)/(hr).

For room *A* this would be equal to $4141/150 = 27.6$ sq ft

By Means of Electric Heaters. Electric heaters are based on an output of 3413 Btu per kwhr.

For room *A* this would be $4141/3413 = 1.21$ kw heater

In room *A*, 4141 Btu per hr is the heat required to make up the loss through the room boundaries. If unheated outside air is introduced into the room, additional heat is required to raise this air from 0 to 70 deg, the temperature maintained in the room. This is calculated by the formula

$$\text{Btu} = 1.08 \times \text{cfm} \times t_d$$

In this case, t_d, the temperature difference, is equal to (70 − 0) or 70 F.

By Means of Hot-air Blast. Hot-blast heating is based on the following formula:

$$\text{Cfm} = \frac{55.6 \times H}{60 \times t_d} = \frac{H}{1.08 \times (t_i - t_r)}$$

where H = heat loss, Btu per hr

$t_d = t_i - t_r$ = difference between inlet air temperature and desired room temperature

55.6 = cfm of air heated 1 deg by 1 Btu at 70 deg which is the temperature at which the system capacity is rated

Assume room *A* to be separately heated and that a 5-min air change is desired with the heating.

$$\text{Cfm to be supplied} = \frac{1{,}120 \text{ cu ft}}{5 \text{ min}} = 224 \text{ cfm}$$

The heat given off by electrical machinery, such as motors or generators, is calculated by determining the Btu equivalent of the electrical loss in the motor or generator.

Example. A 50-hp motor, with an electrical efficiency of 88 percent and with 12 percent of the input energy lost as heat. The input energy, in horsepower, is $50 \div 0.88$ or 56.8 hp. As the output is 50 hp, the heat equivalent of $56.8 - 50$ or 6.8 hp is given off as heat. As 1 hp = 2546 Btu per hr, the total heat given off $= 6.8 \times 2546 = 17{,}300$ Btu per hr.

If a diesel engine is cooled either directly or indirectly by sea water, the heat given off by the cylinders and pistons is carried overboard by the sea water. However, if the engine is installed with an air-cooled radiator, as is generally the case with emergency generator units located above the water line, the heat given off by the radiator is considerable—about one-third of the total heat value in the fuel. In addition, the heat radiated from the exhaust manifold and the heat loss from the electrical generator should be considered. Tests made on air-cooled emergency generator units indicate that approximately one-half of the heat value in the fuel burned is given up to the surrounding air. This indicates the necessity for an adequate supply of ventilating air to spaces housing such a unit.

In determining the ventilation requirements of a main machinery space, the entire space should be arbitrarily divided up into a number of zones or compartments, and the heat liberated in each zone should be calculated in the manner indicated above. All auxiliaries, steam pipes, heaters, boiler surfaces, etc., should be considered. Having determined the total heat liberated in such a zone, the allowable temperature rise in that zone should be decided on, and the air flow to that zone determined, as follows:

$$C = \frac{H}{w \times 60 \times 0.24 \times t_r} = \frac{H}{14.4 \times w \times t_r}$$

where C = air required, cfm

H = total heat liberated in the zone, Btu per hr

w = specific weight of air at the supply temperature, lb per cu ft

t_r = desired temperature rise of the air, deg F

As the outside air temperature will not generally exceed 90 F, the value of w at this temperature is 0.0723 lb per cu ft, and the above may be written

$$C = \frac{0.96 \times H}{t_r}$$

Special Features. Although the heat in a main machinery space is liberated over a considerable vertical depth, the ventilating air should be generally supplied at the lower levels, so that the lower and operating spaces will be maintained at a comfortable temperature. The average temperature rise at working levels should not exceed about 20 F. The natural tendency of heated air to rise will sweep the heated surfaces above the lower levels.

Consideration should be given to the areas generally occupied by the operators. The operating station, for example, should be kept cooler than less frequented areas, such as behind the boilers.

If an exhaust system is installed, the inlets for heated air should be located close to any "hot spots" to lead the hot air away from the operating personnel.

HYPERBOLIC FUNCTIONS

The **hyperbolic sine, hyperbolic cosine,** etc., of any number x, are functions of x which are closely related to the exponential e^x, and which have formal properties very similar to those of the trigonometric functions, sine, cosine, etc. Their definitions and fundamental properties are as follows (see also p. 127; graphs, p. 175; table, p. 60; series, p. 161):

$$\sinh x = \tfrac{1}{2}(e^x - e^{-x});\ \cosh x = \tfrac{1}{2}(e^x + e^{-x});\ \tanh x = \sinh x/\cosh x;$$
$$\operatorname{csch} x = 1/\sinh x;\ \operatorname{sech} x = 1/\cosh x;\ \coth x = 1/\tanh x;$$
$$\cosh^2 x - \sinh^2 x = 1;\ 1 - \tanh^2 x = \operatorname{sech}^2 x;\ 1 - \coth^2 x = -\operatorname{csch}^2 x;$$
$$\sinh(-x) = -\sinh x;\ \cosh(-x) = \cosh x;\ \tanh(-x) = -\tanh x;$$
$$\sinh(x \pm y) = \sinh x \cosh y \pm \cosh x \sinh y;$$
$$\cosh(x \pm y) = \cosh x \cosh y \pm \sinh x \sinh y;$$
$$\tanh(x \pm y) = (\tanh x \pm \tanh y)/(1 \pm \tanh x \tanh y);$$
$$\sinh 2x = 2 \sinh x \cosh x;\ \cosh 2x = \cosh^2 x + \sinh^2 x;$$
$$\tanh 2x = (2 \tanh x)/(1 + \tanh^2 x);$$
$$\sinh \tfrac{1}{2}x = \sqrt{\tfrac{1}{2}(\cosh x - 1)};\ \cosh \tfrac{1}{2}x = \sqrt{\tfrac{1}{2}(\cosh x + 1)};$$
$$\tanh \tfrac{1}{2}x = (\cosh x - 1)/(\sinh x) = (\sinh x)/(\cosh x + 1).$$

The hyperbolic functions are related to the rectangular hyperbola, $x^2 - y^2 = a^2$ (Fig. 12), in much the same way that the trigonometric functions are related to

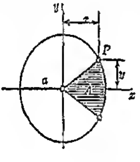

Fig. 11.

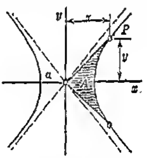

Fig. 12.

the circle $x^2 + y^2 = a^2$ (Fig. 11); the analogy, however, concerns not angles but areas. Thus, in either figure, let A represent the shaded area, and let $u = A/a^2$ (a pure number). Then for the coordinates of the point P we have, in Fig. 11, $x = a \cos u$, $y = a \sin u$; and in Fig. 12, $x = a \cosh u$, $y = a \sinh u$.

The **inverse hyperbolic sine** of y, denoted by $\sinh^{-1} y$, is the number whose hyperbolic sine is y; that is, the notation $x = \sinh^{-1} y$ means $\sinh x = y$. Similarly for $\cosh^{-1} y$, $\tanh^{-1} y$, etc. These functions are closely related to the logarithmic function, and are especially valuable in the integral calculus. For graphs, see p. 175.

$$\sinh^{-1}(y/a) = \log_e(y + \sqrt{y^2 + a^2}) - \log_e a;$$
$$\cosh^{-1}(y/a) = \log_e(y + \sqrt{y^2 - a^2}) - \log_e a;$$
$$\tanh^{-1}\frac{y}{a} = \tfrac{1}{2}\log_e \frac{a + y}{a - y};\quad \coth^{-1}\frac{y}{a} = \tfrac{1}{2}\log_e \frac{y + a}{y - a}.$$

The **Gudermannian** of x (written gd x) is an angle u such that $x = \log_e \tan(\tfrac{1}{4}\pi + \tfrac{1}{2}u)$. See Smithsonian Tables of the Hyperbolic Functions.

The **anti-gudermannian** of an angle u, denoted by $\operatorname{gd}^{-1} u$, is a number defined by $\operatorname{gd}^{-1} u = \log_e \tan(\tfrac{1}{4}\pi + \tfrac{1}{2}u) = \int \sec u\, du = \sinh^{-1}(\tan u) = \cosh^{-1}(\sec u) = \tanh^{-1}(\sin u) = 2 \tanh^{-1}(\tan \tfrac{1}{2}u)$. When u is small, $\operatorname{gd}^{-1} u = u + \tfrac{1}{6}u^3 + \tfrac{1}{24}u^5 + \tfrac{61}{5040}u^7 + \ldots$

ANALYTICAL GEOMETRY

THE POINT AND THE STRAIGHT LINE

Rectangular Co-ordinates (Fig. 1). Let $P_1 = (x_1, y_1)$, $P_2 = (x_2, y_2)$. Then, distance $P_1P_2 = \sqrt{(x_1 - x_2)^2 + (y_1 - y_2)^2}$; slope of $P_1P_2 = m = \tan u = (y_2 - y_1)/(x_2 - x_1)$; co-ordinates of mid-point are $x = \frac{1}{2}(x_1 + x_2)$, $y = \frac{1}{2}(y_1 + y_2)$; co-ordinates of point $(1/n)$th of the way from P_1 to P_2 are $x = x_1 + (1/n)(x_2 - x_1)$, $y = y_1 + (1/n)(y_2 - y_1)$.

Let m_1, m_2 be the slopes of two lines; then, if the lines are parallel, $m_1 = m_2$; if the lines are perpendicular to each other, $m_1 = -1/m_2$.

Equations of a Straight Line.

1. Intercept Form (Fig. 2): $\dfrac{x}{a} + \dfrac{y}{b} = 1$. ($a$, b = intercepts of the line on the axes.)

2. Slope Form (Fig. 3): $y = mx + b$. ($m = \tan u$ = slope; b = intercept on the y-axis; see also Fig. 2, p. 174.)

3. Normal Form (Fig. 4): $x \cos v + y \sin v = p$. (p = perpendicular from origin to line; v = angle p makes with the x-axis.)

4. Parallel-intercept Form (Fig. 5): $\dfrac{y - b}{c - b} = \dfrac{x}{k}$. ($b$, c = intercepts on two parallels at distance k apart.)

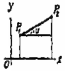

Fig. 1.

Fig. 2.

Fig. 3.

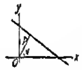

Fig. 4.

Fig. 5.

5. General Form: $Ax + By + C = 0$. [Here $a = -C/A$, $b = -C/B$, $m = -A/B$, $\cos v = A/R$, $\sin v = B/R$, $p = -C/R$, where $R = \pm\sqrt{A^2 + B^2}$ (sign to be so chosen that p is positive).]

6. Line Through (x_1, y_1) with Slope m: $y - y_1 = m(x - x_1)$.

7. Line Through (x_1, y_1) and (x_2, y_2): $y - y_1 = \dfrac{y_2 - y_1}{x_2 - x_1}(x - x_1)$.

8. Line Parallel to x-axis: $y = a$; to y-axis: $x = b$.

Angles and Distances.

If u = angle between two lines whose slopes are m_1, m_2, then

$$\tan u = \frac{m_2 - m_1}{1 + m_2m_1}.$$

If parallel, $m_1 = m_2$.
If perpendicular, $m_1m_2 = -1$.

If u = angle between the lines $Ax + By + C = 0$ and $A'x + B'y + C' = 0$, then

$$\cos u = \frac{AA' + BB'}{\pm\sqrt{(A^2 + B^2)(A'^2 + B'^2)}}.$$

If parallel, $A/A' = B/B'$.
If perpendicular, $AA' + BB' = 0$.

The equations of the bisectors of the angles between the two lines just mentioned are

$$\frac{Ax + By + C}{\sqrt{A^2 + B^2}} \mp \frac{A'x + B'y + C'}{\sqrt{A'^2 + B'^2}} = 0$$

Where heat-liberating units, such as auxiliary generators, are located toward the sides of the ship, the supply air ducts should discharge outboard of these units, as the natural tendency of the air to rise in the center up the machinery casing will induce air flow from the sides toward the center of the space. Supply outlets should not discharge directly toward switchboards or electrical controls, as the moisture in the air will affect these elements. Outlet terminals, particularly of larger sizes, should be fitted with adjustable dampers, which may be set to control the flow as required. This is particularly important for vessels operating in widely varying temperatures, as the machinery spaces may otherwise be unduly cold when in port in cold climates.

CARGO SPACES

General. Cargo spaces requiring ventilation include lower holds and 'tween-deck spaces for stowage of dry cargo or cased liquids. The cargo tanks of bulk-oil tankers are not ventilated when carrying cargo oil, but temporary means for ventilation of cargo tanks when empty are necessary in order to "gas-free" the tank and purify the air prior to entry by personnel. As the prime purpose of a cargo carrier is to deliver cargo in a satisfactory condition at its destination, proper care during transit is essential.

The condition of air in, and air supply to, dry cargo spaces has only recently received proper attention. Most ships afloat today are equipped only with natural ventilation of cargo spaces, depending on cowled intake and exhaust ventilators for air circulation. Some forms of cargo are "inert" and require no ventilation as long as the temperature of cargo and the air in the hold are constant; but very few trade routes lie completely in a zone of constant air and sea temperature. All sea air is humid and contains a considerable amount of moisture. If a ship is loaded in warm weather and the hatches are sealed prior to sailing, considerable moisture is held in the warm air. When the ship enters cooler weather, the moisture in the air condenses on the cooled ship structure or cargo, unless replaced with drier air. Similarly, when the ship is loaded in cold weather and proceeds to a warmer climate, if warm (and moisture-laden) air is pumped through the hold, its moisture will condense on the cold surfaces, and sweat appears.

Air of 100 percent relative humidity, at a temperature of 80 F, contains 156 grains water vapor per lb air. At 40 F it contains only 36 grains water vapor per lb air; hence a large amount of moisture will condense on the cooled surfaces in proceeding from warm to cold climates. Positive means of replacing the moisture-laden air should be provided.

Ventilation of cargo spaces is also necessitated by the nature of the cargo itself. Certain commodities like chocolate, lard, cheese, and alcoholic beverages are damaged by even moderate heat. Heat will also affect wet or damp hygroscopic cargoes like green lumber, grain, hides, and other vegetable or animal products, and cause them to release part of their inherent moisture as water vapor, which will settle on cooler surfaces or be absorbed by other hygroscopic cargo, thus damaging both commodities. Other commodities, chiefly of vegetable or animal origin, are subject to spontaneous heating and, unless kept at a proper temperature by removal of this heat, they will spoil. Still other cargoes will give off objectionable odors, which may be absorbed by other parts of the cargo carried. Adequate provision should be made for air circulation around and through such cargoes, so that heat or vapor may be released through the cargo itself. The designer must provide

found among various authorities. Despite such variations, friction-loss calculations are absolutely necessary in designing a system, and the data available adequately fulfill their purpose.

Friction loss is expressed in inches water gage. It may also be expressed in terms of velocity head, which is related to the velocity of standard air by the following formula:

$$H_v = \left(\frac{V}{4{,}005}\right)^2$$

where H_v = velocity head, in. water gage
V = velocity of air, fpm

Velocity head is frequently expressed in terms of so many diameters of straight circular pipe. Consequently any fitting may be designated as the frictional equivalent of a certain length of straight pipe expressed in diameters. The length of pipe equivalent to one velocity head depends on the duct construction, the usual range being between 39 and 50 diameters. For this discussion, however, loss will be expressed in terms of velocity head, H_v.

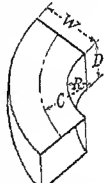

FIG. 13.—Elbow dimensions.

Straight-duct friction losses in inches water gage per 100 ft duct length are shown in Fig. 12. This chart plots pressure loss against cfm for various sizes of circular pipes. If a rectangular duct is being considered, it must first be converted by means of Table 4 to the circular duct having the same friction when carrying a given amount of air. The friction reading from Fig. 12, divided by 100 and multiplied by the length of duct in feet, will give the pressure loss of any given run of duct in inches water gage.

Before treating the subject of **elbows**, the following should be defined:

Center-line Radius Ratio. Center-line radius of an elbow divided by the width of the duct in the direction of the bend $= \frac{C}{W}$.

Inside-radius Ratio. Inside radius of an elbow divided by the width of the duct in the direction of the bend $= \frac{R}{W}$.

Aspect Ratio of Elbow. Depth of duct divided by the width of duct in the direction of the bend $= \frac{D}{W}$.

Aspect Ratio of a Duct. Long side divided by short side.

The pressure loss in an elbow varies with both the radius ratio and the aspect ratio. Figure 14 gives the loss in terms of velocity head, plotted against the inside-radius ratio. If the aspect ratio is greater than unity, it may be neglected; if less than unity, the value read from Fig. 14 should be multiplied by factor (*a*) taken from Fig. 15. If an elbow is less than 90 deg, the loss is less in direct proportion; if an elbow is more than 90 deg, the loss increases by approximately 75 percent of the greater angle. For example, the loss in a 45-deg bend will be 50 percent of that in a 90-deg bend of the same characteristics; for one of 135 deg the loss will be 100 + (50 × 0.75)

for the ultimate removal of such heat and vapor and the supply of replenishing air.

Other cargoes, inert of themselves, are seriously damaged by heat or moisture. Metals, machinery, and metal containers are rusted; foodstuffs are made unpalatable; textiles are discolored and mildewed; fibers and grains are fermented; and mineral or chemical products are dissolved by excessive moisture. For ships frequently carrying such cargoes, a system for artificially controlling the moisture content of the air may be desirable. Such a system is generally designed as an integral part of the cargo ventilating system.

When a cargo ventilating system is designed, the inlet to, and the outlet from, a given space should be as far removed from each other as feasible. The inlet or supply may be at one end of the hold and the outlet or exhaust at the other end to ensure complete circulation through the space. If this is not possible, the terminals may be carried out approximately to the sides of the ship by means of ducts, lying between deck beams if the ship is transversely framed. Ducts and terminals in cargo spaces should be well protected, to prevent damage while cargo is being loaded. Also, the terminals should be so arranged that stowage of cargo will not obstruct the egress or ingress of air. If the hold is of considerable size, several points of inlet and outlet should be provided.

Conditions. The nature of the commodities carried is so varied as to make precise statements of desirable conditions difficult, if not impossible. However, as a general guide, ventilating systems should provide an air change in 15 to 30 min, based on the grain capacity of the empty hold. This will permit the air to be changed, and any heat or vapor removed, at such a rate that cargo will not be damaged by usual variations in outside air temperature. If the spaces are to carry inflammable cargoes, or cargoes giving off inflammable vapors, special consideration is necessary.

Cargoes of "inherent vice," *i.e.*, those which are not inert and give off spontaneous heat or moisture, may require the inclusion of a system giving humidity control. Here again the establishment of accurate standards is difficult, owing to the varying nature of the cargo. Present practice for ships carrying 8,000 to 10,000 tons of cargo is to install a system that will permit the circulation of approximately 3,000 cfm air through the dehumidifying equipment. The latter should be designed to remove approximately 160 lb moisture per hr from 3,000 cfm outdoor air, the outdoor air being supplied at 88 F dry bulb and 80 F wet bulb, or a relative humidity of 75 percent. The relative humidity of the dehumidified air, assuming a temperature of 150 F, will be about $4\frac{1}{2}$ percent. A psychrometric chart, showing the relations among dry-bulb temperature, wet-bulb temperature, relative humidity, and moisture content of air, is shown in Fig. 1.

A dehumidifying system of the capacity stated will suffice to maintain cargo holds and their contents in good condition. It is rarely necessary to dehumidify all cargo holds simultaneously. Such a system is frequently operated on one or two holds at a time, until proper conditions in them are obtained; then the treatment is switched to another hold or holds. It may be unnecessary to treat certain holds at all during a voyage, depending on the nature of the cargo in them.

Methods. Natural ventilation of cargo spaces is satisfactory where the ship carries cargo unaffected by temperature or humidity changes, such as a bulk ore carrier. It is also fairly satisfactory where inert cargoes are

carried on routes of uniform temperature. However, the majority of general cargo ships operate in widely varying climates, most cargoes are susceptible to temperature and humidity changes, and natural ventilation is relatively inflexible. At best, it offers a means for circulating a limited amount of air, around and through the hold or space in fair weather. In rough or rainy weather, its usefulness is greatly decreased by the need for maintaining weathertightness and preventing rain, spray, or solid water from entering the inlet cowls. Frequently the need for ventilation is greatest at such times and, as a result, it is impossible to maintain the hold conditions at a satisfactory standard.

Where natural ventilation is fitted, several ventilating trunks must be fitted for each hold; one or more for supply air and an equal number for exhaust. Inlet and outlet heads may be of conventional cowl type, capable of being turned in any direction, so that the inlets may be trimmed into the wind and the outlets trimmed away from the wind to permit circulation. Such weather openings must be high enough off the deck to prevent rough seas from entering the cowls; and in rainy weather they must be trimmed away from the weather. Kingposts, where fitted, may be used as trunks, with proper heads at their tops.

Mechanical ventilation is far more satisfactory than natural ventilation, owing to its flexibility of use and operation. Smaller weather openings are possible. Ducts for supply and exhaust may be smaller, as the friction losses may be much greater; greater volumes of air are obtainable; and it is possible to operate the system in bad weather. Weather heads do not require constant trimming into or away from the wind.

Mechanical systems embrace the following types:

1. Mechanical supply, with natural exhaust.
2. Natural supply, with mechanical exhaust.
3. Mechanical supply, with mechanical exhaust.
4. Mechanical supply and exhaust, with humidity control.

Mechanical supply, with natural exhaust, is most frequently employed, as it overcomes the main objections to natural ventilation at minimum installed cost. Where kingposts are fitted, they may be utilized as exhaust outlets. However, the use of kingposts as exhaust trunks is likely to result in condensation of moisture within the kingpost, with the consequent dripping of condensed moisture to the bottom interior of the post.

Natural supply, with mechanical exhaust, is objectionable in that the natural inlets are subject to many of the undesirable features of natural ventilation, unless care is taken to prevent spray and rain from entering the inlets.

Mechanical supply, with mechanical exhaust, overcomes many of the disadvantages of natural ventilation, but its higher first cost is an objection, owing to the duplication of mechanical equipment on inlet and outlet. If the attendant ducts are properly arranged, a uniform circulation of air throughout the cargo space is obtainable, as the supply air may enter on one side of the cargo space and be withdrawn from the opposite side of the space. If the fans are reversible, even greater flexibility is obtained, as the flow direction may likewise be reversed. Where a cargo giving off odor, moisture, or heat is stowed on one side of the ship, it may be advisable to supply the air from the opposite side to avoid tainting or damaging other commodities in the same hold.

Mechanical supply and exhaust, with humidity control, has been recently developed and has much to recommend it, where cargoes of "inherent

or 137.5 percent of that for the 90-deg bend. For figuring pressure loss, a vaned elbow should be considered as a series of separate standard elbows, the vanes being so located that the radius ratio is the same in all of them. The resulting inside-radius ratios for elbows with 1, 2, or 3 vanes are given in Fig. 18. From these values, the friction loss can be read directly from Fig. 14.

Terminals and fittings must be considered as special problems in each case, since there are too many types and variations for much generalization. Table 5 lists friction losses for typical marine equipment. The values given can serve as guides in estimating losses for similar cases. The values given for vendor's equipment should be used only for preliminary determinations.

FIG. 14.—Friction loss in 90-deg elbows.

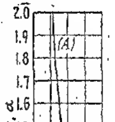

FIG. 15.—Aspect ratio factors.

When the equipment to be used is definitely known, exact loss figures should be obtained from the manufacturer.

Example. The following system loss is calculated by the friction-loss method. Figure 16 shows a typical duct layout for quarters. It will be assumed that these spaces are served by fan 2 shown in Fig. 6 and that the run to outlet G has the highest resistance of the runs on the system served by this fan. This run will, therefore, determine the fan static pressure to be specified. The pressure-loss calculations for this system are shown in Table 6.

Since the fan outlet size gives a reasonable velocity for the initial runs of duct, this size will be used for establishing the friction-loss factor for all straight ducts in the run. This appears in Table 6 as items 7 and 12 and is equal to 0.27 in. water gage per 100 ft of duct. The vertical line in Fig. 12 corresponding to this value will, therefore, hold throughout the system, and its intersection with the horizontal cfm lines will determine the proper size of round duct for any air quantity. The round duct size is then converted to a rectangular duct suitable for the installation by means of Table 4. For example, the proper size for 300 cfm is an 8 in. diam duct, which in turn is the frictional equivalent of a rectangular duct 5 by 11 in., 6 by 9 in., 4 by 14 in., etc. A 9 by 6 in. duct is chosen as the most suitable for the run between rooms *D* and *E*. The sources of other values used are explained in the notes in Table 6.

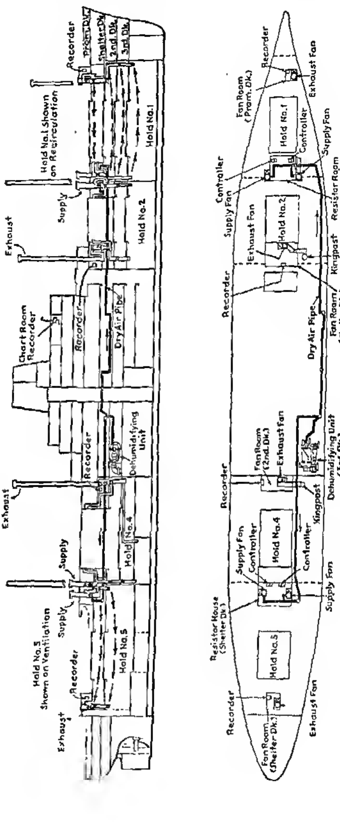

FIG. 7.—Dehumidification system on S.S. "African Comet."

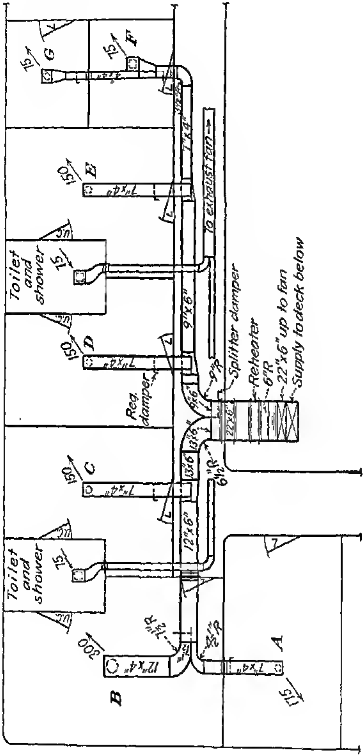

FIG. 16.—Typical duct layout.

vice" are carried or where extreme variations of outside temperature are met. This method employs a normal mechanical supply and exhaust system, with the addition of a central dehumidifying system selectively serving all or some of the holds.

A diagrammatic arrangement for a typical installation is shown in Fig. 7. The ship illustrated is a U.S. Maritime Commission cargo ship of the "African Comet" type. The installation there shown comprises a dehumidifying unit centrally located, which discharges dry air through a dry-air pipe to any of the holds arranged for control. Each hold is fitted with a supply and an exhaust fan, with ducts and dampers so arranged that the following are possible:

1. *Straight Ventilation.* Outside air drawn from atmosphere by supply fan and discharged to hold and 'tween deck. Exhaust air withdrawn from hold and 'tween deck by exhaust fan and discharged to atmosphere.

2. *Recirculation.* Dry air supplied from dehumidifying unit via dry-air pipe to suction of supply fan. Supply fan also takes suction from 'tween-deck space. The supply fan discharges a mixture of partly dehumidified air to the lower hold, absorbing moisture from the air therein, and the humidified air is withdrawn from the lower hold by the exhaust fan, which discharges part to the atmosphere, the balance returning to the supply fan inlet by way of the upper 'tween deck. The moisture removed from the hold air is that contained in the air discharged to the atmosphere. The volume of the air discharged to the atmosphere is, of course, equal to the volume of the dry air entering the hold. By proper control of the relative volumes of dry and recirculated air, the desired air condition is maintained.

Each hold is fitted, near its exhaust fan, with a recorder, which withdraws a continuous sample of the air being circulated and traces on a paper tape the actual temperature of the air leaving the hold and the relative humidity. As long as the dew point is below the temperature of the cargo, sweat will not be deposited on the cargo.

It is not necessary to supply dehumidified air from the central unit at all times, in order to maintain proper conditions of the air in the hold. Straight ventilation should be used whenever the temperature and humidity of outside air are suitable.

Refrigeration is another method of conditioning cargo spaces. This subject is covered elsewhere under the subject of Cargo Refrigeration (see p. 1882).

Calculations. A typical case showing the importance of ventilation to cargo holds follows.

Example. Consider a single hold, loaded with 1,000 tons of steel, at a temperature of 40 F. If the hold volume is 60,000 cu ft, the steel will occupy 4,600 cu ft, and the air the balance, or 55,400 cu ft. If the relative humidity during the loading period was 70 percent, the air will contain 25 grains moisture per lb air. As air at this condition weighs 0.079 lb per cu ft, the weight of the air in the hold at time of loading is 4,370 lb, of which about 16 lb is water vapor.

Assume the ship sails into a warm climate, where the air temperature is 80 F with a relative humidity of 90 percent. Air at this condition has a dew point of 76.5 F and contains 138 grains water vapor per lb. If air is then circulated through the hold, the weight of air therein will decrease from 4,370 to 3,940 lb, but the moisture content will have increased from 16 to 78 lb. If the temperature of the steel had not been raised above the dew point by ventilation, the moisture would condense on the cold steel and cause it to rust. In order to prevent sweat and condensation, the temperature of the cargo must be maintained above the dew point of the air in the hold.

[b] Inches of water.

It has been stated that the run to outlet G has the greatest resistance on the system. Any other run, such as that to outlet A, will therefore, if based on a factor of 0.27 in., have a lower resistance and tend to draw more than its share of the air. This is rectified by the splitter damper provided at the split between the two main branches. If, however, a short branch is taken off near the fan, its resistance would be far less than that in the longest run. Such a duct would have to be restricted or "dampered down" considerably to reduce its air volume to the proper quantity. The same result can be accomplished more practically by reducing the size of the branch and thus increasing the air velocity and resistance. This should be done only to a point where the velocity will not exceed the reasonable limits given above.

The method of balancing the friction in the branches of a system can be illustrated by Fig. 16. If the fan were selected on the basis of the run to outlet G, the pressure at a point in the 22 by 6 in. duct between the reheater and the split in the ducts would be 1.02 in. minus 0.86 in. (cumulative total of items 1 to 9) or 0.16 in. For outlet A to be in balance with outlet G, the resistance between the 22 by 6 in. duct and outlet A must be made equal to that between the 22 by 6 in. duct and outlet G (total of items 10 to 13) or 0.16 in. Since the loss in the diffuser is known and that in the elbows can be estimated, these can be subtracted from 0.16 in. to give the loss for the 15 ft straight duct. Con-

The purpose of **ventilation** of a cargo hold, for inert cargoes such as the above, is to control their temperature and maintain it above the dew point of the air in the hold. The purpose of **humidity control** is to reduce the dew point of the air and thus prevent sweat and condensation either on the steel of the ship or on the cargo itself.

Example. A simplified typical calculation for the mechanical hold ventilating fans of a ship is as follows:

Volume of hold, cu ft (grain capacity) = 75,000
Air changes per hour, assumed = 3

$$\text{Air to be circulated, cfm} = \frac{75{,}000 \times 3}{60} = 3{,}750$$

Allow for fan design, cfm = 4,000
Static pressure loss, P_s, in. water:

Inlet head	0.2
Inlet duct friction	0.3
Loss through hold	0.5
Outlet duct friction	0.1
Outlet head	0.2
Total static pressure loss, in. water	1.3

Allow for fan design: $P_s = 1.5$ in.

$$\text{Air hp} = \frac{\text{cfm} \times P_s}{6{,}356} = \frac{4{,}000 \times 1.5}{6{,}356} = 0.95$$

The static efficiency of the fans at their rated performance varies from 50 to 70 percent, depending on the actual design. Assume here a static efficiency of 60 percent. Then,

$$\text{Bhp required of motor} = \frac{\text{air hp}}{\text{static efficiency}} = \frac{0.95}{0.60} = 1.58$$

Hence a standard rated 2-hp motor would be fitted.

Special Features. Ventilating ducts should be laid out to offer as little obstruction to cargo stowage as possible. They should lie between deck beams and frames. Ducts or trunks which do not lie close to the ship structure or which cause broken stowage are to be avoided, for they are likely to be damaged, and they reduce the cubic space available for cargo and the ship's potential earning capacity. Protection from damage when cargo is being worked should be provided by strong guards. The terminals should have ample guards to prevent blocking the air flow and should not discharge the air stream directly against the cargo. The possibility of moist inlet air or moisture condensed within the duct should be considered.

EQUIPMENT

Fans. In order to create a movement of air by mechanical means in a fan, the energy of the driving motor must be converted into kinetic or velocity energy by rotation of a rotor. The rotor may create air velocity by several means, the difference being mainly whether the velocity is created in a **centrifugal** direction (normal to the axis of the rotor) or in an **axial** direction (parallel to the axis of the rotor). Both centrifugal- and axial-flow fans are used in ventilation, the selection of type being governed by the requirements.

Centrifugal fans are broadly divided into two types, depending on the inclination of the blades comprising the rotor. The blades of one type are

verting this to the basis of 100 ft of duct, the diameter of duct to be used can be read from Fig. 12 and the rectangular equivalent from Table 4. A system with the principal branches balanced in this manner requires but slight equalizing with regulating dampers, and duct sizes are reduced to a minimum.

Duct Construction. Most ducts are constructed of galvanized sheet steel, the gage of which should be selected approximately on the basis of the dimension of the greater side.

Exposed vertical ducts:
No. 18 or No. 16 U.S.S. gage depending on size and chance of damage
Horizontal and concealed vertical ducts:

Over 24 in.	No. 16 U.S.S. gage
12–24 in.	No. 18 U.S.S. gage
6–12 in.	No. 20 U.S.S. gage
Less than 6 in.	No. 22 U.S.S. gage

The method of construction will depend on the available shop facilities, but usually ducts of No. 18 U.S.S. gage or heavier have riveted or spot-welded seams, while those of lighter metal are grooved, double-seamed, or Pittsburgh-locked. All seams must be made airtight with a sealing compound. Ducts should be smooth inside with joints lapped in the direction of the air flow. Sufficient flanged joints, fitted with suitable gasket, should be provided to make all ducts portable. Hangers should rigidly support all

curved **forward**; for the other type they are curved **backward**. This difference results in entirely different performance characteristics. Figures 8 and 9 show the type of blades and the performance characteristics for forward-curved and backward-curved blades, respectively. For forward-curved blades, the static pressure at no delivery is a maximum; as the air flow increases, the static pressure falls, then rises again to a peak, and again falls

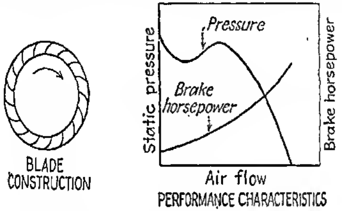

FIG. 8.—Centrifugal fan. Forward-curved blades.

as the flow increases still further. For the backward-curved blades, the static pressure at no delivery is a certain value; as the air flow increases, the static pressure rises to a peak and then falls off. The power requirements are also shown. The power for forward-curved blades continually rises as the flow increases; for backward-curved blades the power rises to a maximum and then decreases. Where a ventilating system, designed for a certain flow-pressure relation, may on occasion pass a larger flow at lower pressure, the use

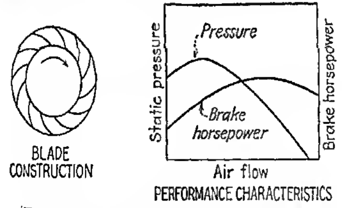

FIG. 9.—Centrifugal fan. Backward-curved blades.

of a forward-curved blade may overload the driving unit. For such systems the backward-curved blade should be used. However, most ventilating-duct systems are so designed that increased flow is obtained with only an attendant increase in static pressure; therefore the forward-curved blades are suitable. For a given volume and pressure condition, forward-curved-blade fans will operate at a lower tip speed and generally will be quieter than backward-curved fans.

ductwork, spacing to be not over 8 ft. All ducts with a side of 24 in. or more, and other ducts as necessary, should be stiffened with angle bars welded or riveted to the outside to prevent panting. In any case, where it is impossible to avoid a pipe, structural angle, or other obstruction passing through or cutting into a duct, a "teardrop"-shaped easement of sheet metal should be placed around it to lessen the disturbance of the air stream. A duct with an aspect ratio greater than 4 should have a dividing diaphragm to give stiffness and aid the air flow.

Plate trunks are used in lieu of sheet-metal ducts,

1. When a watertight compartment is penetrated, in which case the ventilation trunk must be of the same strength as the boundaries penetrated, to ensure the watertightness of the compartment violated.

2. In cargo holds and other places where lighter material would be subject to damage.

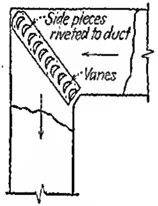

FIG. 17.—Square elbow with double radius turning vanes.

3. If the structure or space arrangements are such that it is advantageous to use a bulkhead as one side of the ventilation trunk. In this case the adjacent sides of the duct are welded to the bulkhead.

Plate trunks should be all welded for airtightness and should be either flanged for portability (small sizes only) or have handholes provided for painting and inspection.

Elbows should have an inside-radius ratio of 1 or greater whenever possible. Whenever the inside-radius ratio is less than 0.5 and in all cases in which the elbow discharges to or draws directly from the weather, vanes should be inserted. The vanes should run the full angle of the elbow and the full depth of the duct. They should be concentric to the inside and outside radii, except in a transforming elbow in which case they should divide the two sizes of ducts in the same proportion. Figure 18 shows the proper location of the vanes in any elbow.

For the case of 90-deg elbows, in which it is impossible to get any reasonable radius, there are available double-radius types of turning vanes which are installed diagonally in the square elbow. These vanes are designed so that the free area between them is equal to the cross-sectional area of the straight duct, thus giving a uniform velocity through the turn. These are sold in various sizes to suit different sizes of ducts.

Axial-flow fans, as used for ventilation, are broadly divided into two classes. **Propeller fans** are similar to the conventional domestic fan and are often built without a surrounding duct. For supply to or exhaust from a space such as a room or passage, they are mounted in an aperture cut into a bulkhead or deck. Having no connecting ducts, fans for such application are not used for high static pressures; their chief use is the moving of air

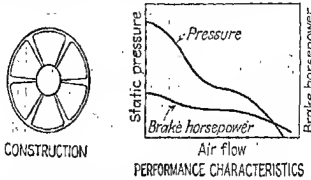

FIG. 10.—Propeller fan.

against relatively low resistance. Bracket fans, with the fan propeller directly mounted on the motor shaft and with merely a wire guard surrounding the blades, are used where local circulation of air within a space is desired. Fans of the propeller type, built inside a surrounding duct and connected to a supply or exhaust duct system, are capable of developing higher pressures and are conventionally termed **axial-flow fans.** They are built with fixed guide vanes at the inlet or outlet, to rectify the rotation of the air stream.

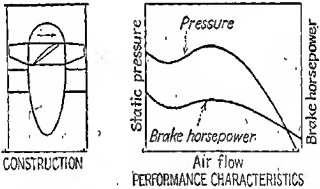

FIG. 11.—Axial-flow fan.

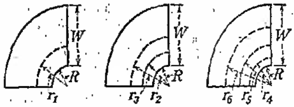
So defined, axial-flow fans are suitable for moving large volumes of air against moderate, and even high, static pressures; when working against considerable pressure, they are somewhat noisier than a centrifugal fan for the same duty. The blade type and typical characteristic curves for propeller and axial-flow fans are shown in Figs. 10 and 11, respectively.

Ducts. In laying out any duct system the following general rules should be observed:

1. Make runs as short as possible.



R = Inside radius of elbow
F = Vane factor
r = Radius of vane = R (1+F)

FIG. 18.—Equivalent of vaned elbows.

No. of vanes	1		2			3

0.75	0.53	1.88							
1.0	0.42	2.38							

[a] Use as inside-radius ratio for determining loss from Fig. 14.

Hangers may be of either angle or flat bar depending on the size of the duct and the distance from the deckhead. The bar should be as light as possible consistent with rigidity. A simple effective hanger consists of an angle welded vertically to the deckhead and bolted to the side angles of a

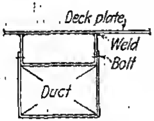

FIG. 19.—Flat-bar hanger.

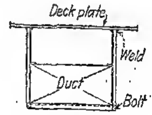

FIG. 20.—Angle-bar hanger.

connection flange by three or more of the flange bolts. Two other typical types are shown in Figs. 19 and 20.

Branch Connections. The preferred take-off for a branch is a split from the main duct. The division should be in proportion to the cfm in the two small ducts which can then be transformed to their proper size, based on equal friction, velocity, or other method.

2. Keep the number of turns and transformations to a minimum and make those that are necessary as easy and conventional as possible.

3. Round, square, and rectangular ducts are preferred in that order, with the last-named as nearly square as possible.

4. Check the structure, piping, wireways, and fixtures carefully.

5. Headroom and appearance should always be considered.

With these rules in mind, a single line diagram of the system is laid out, showing the general location of all outlets, elbows, branches, etc., and marked with the flow for every section of duct. The duct sizes should then be determined by one of two basic methods: the velocity method or the friction method.

The **velocity method** is based on designated velocities for the various duct sections, with gradual reduction as the air volume gets smaller. The friction losses for the various sections of the run are then calculated separately and added to determine the total. The actual velocities chosen should be governed by the particular case, but Table 3 may be used as a guide.

Table 3. Velocities in Ducts

Air Volume, Cfm	Velocity, Fpm
Less than 1,000	1,000–1,500
1,001–2,000	1,700
2,001–3,000	1,800
3,001–5,000	2,000
5,001–8,000	2,250
8,001 and over	2,500–3,000

This method is easy to apply and gives good results for small systems. For a large system, however, the duct sizes are apt to run somewhat larger than when figured by the friction-loss method.

The **friction-loss method** is based on the choice of duct sizes that will give equal friction per linear foot of duct throughout the length of the run. This method is generally preferred for systems of any complexity and is illustrated below.

The pressure loss for any run is equal to the sum of the pressure losses through all the elements in that run, from intake to discharge. The static pressure of any system, *i.e.*, the pressure that should be maintained by the fan in order to distribute the specified air, is calculated from the run having the highest resistance. This is generally, but not necessarily, the longest run on the system. If a mechanical supply system serves a space with natural exhaust, the fan must overcome the resistance in this natural system, in addition to the resistance in the supply system. Therefore, this must be added to, and considered part of, the run supplying the space. The same situation is, of course, true of a mechanical exhaust system with natural supply.

The flow of gases is a complex subject and, as such, will not be discussed here. The practical application, however, is used in the design of any ventilation system and will be touched on in relation to shipwork. It should be observed that values for friction losses cannot be regarded as exact quantities. Some are based on formulas that cannot be exact for all conditions met in practice; some are obtained from laboratory tests and will vary with the experimenter's interpretations of the results; others are assumptions based on known values for similar shapes, etc. Seemingly insignificant factors such as the type of paint used on the inside of a duct will have an effect on the friction loss. These conditions explain the differences to be

A round duct is generally connected at an angle to the main duct. Care should be taken in locating such a branch since, with supply especially, high-velocity or uneven flow in the main duct may interfere with flow in the branch.

The top take-off is useful in quarters systems where large mains with many branches are run hard under the deck beams. This fitting permits taking off

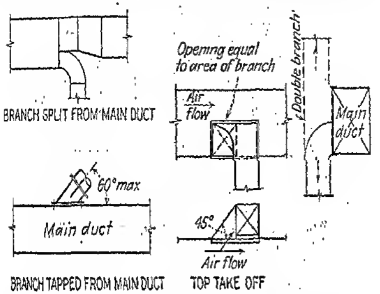

Fig. 21.—Typical branch connections.

and running the branch between the beams. It may be either single or double as shown.

Slip joint is used for connecting sections of sheet-metal duct in locations where there is not sufficient space to make up a flange connection. It is

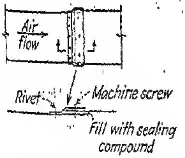

Fig. 22.—Slip joint.

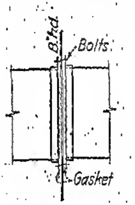

Fig. 23.—Flange connection.

frequently used in branches of a quarters system where the main duct in the passage is too close to the room bulkhead to permit a flange joint.

Flange connection is the most used joint between portable sections of duct and for bulkhead connections where no compensation for the cut is required. The joint is made airtight with gasket and sealing compound. Bolt spacing should be about every 3 in. The weight of the flange angle

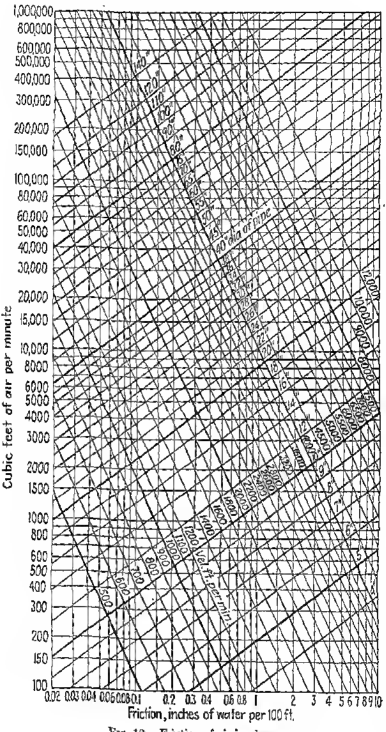

FIG. 12.—Friction of air in pipes.

varies from about 1 by 1 by ⅛ in. to 1½ by 1½ by ¼ in., depending on the size of duct.

Plate coamings must be used wherever a duct passes through or terminates at a deck. Their function is to give a watertight connection around the cut in the deck, to afford compensation for the steel cut away, and to

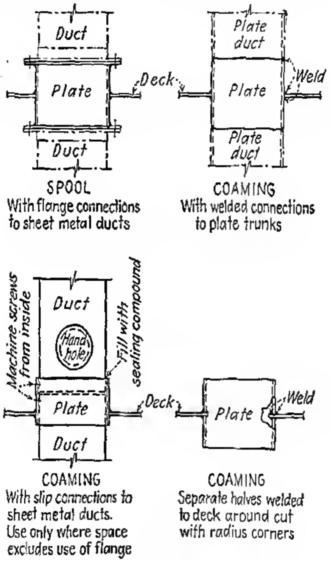

Fig. 24.—Typical coamings.

facilitate installation. They are also the preferred bulkhead connection. With sheet-metal ducts, the flanged coaming or spool is generally used. In cases where a rectangular cut is required in a strength member, a radius corner is generally called for. To meet this condition the corners of the coaming may be rounded, or the rectangular coaming may terminate at the deck outside of the cut. Coamings generally extend 3 in. above and below

The equation of a line through (x_1, y_1) and meeting a given line $y = mx + b$ at an angle u, is

$$y - y_1 = \frac{m + \tan u}{1 - m \tan u}(x - x_1).$$

The distance from (x_0, y_0) to the line $Ax + By + C = 0$ is

$$D = \left|\frac{Ax_0 + By_0 + C}{\sqrt{A^2 + B^2}}\right|$$

where the vertical bars mean "the absolute value of."

The distance from (x_2, y_2) to a line which passes through (x_1, y_1) and makes an angle u with the x-axis, is

$$D = (x_2 - x_1)\sin u - (y_2 - y_1)\cos u.$$

Polar Co-ordinates (Fig. 6). Let (x, y) be the rectangular and (r, θ) the polar co-ordinates of a given point P. Then $x = r\cos\theta$; $y = r\sin\theta$; $x^2 + y^2 = r^2$.

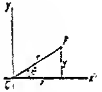

FIG. 6.

Transformation of Co-ordinates. If origin is moved to point (x_0, y_0), the new axes being parallel to the old, $x = x_0 + x'$, $y = y_0 + y'$.

If axes are turned through the angle u, without change of origin,

$$x = x'\cos u - y'\sin u, \quad y = x'\sin u + y'\cos u.$$

THE CIRCLE

(See also pp. 99, 103-105, 109)

Equation of Circle with center (a, b) and radius r:

$$(x - a)^2 + (y - b)^2 = r^2.$$

If center is at the origin, the equation becomes $x^2 + y^2 = r^2$. If circle goes through the origin and center is on the x-axis at point $(r, 0)$, equation becomes $x^2 + y^2 = 2rx$. **The general equation of a circle** is

$x^2 + y^2 + Dx + Ey + F = 0$; it has center at $(-D/2, -E/2)$, and radius $= \sqrt{(D/2)^2 + (E/2)^2 - F}$ (which may be real, null, or imaginary).

The equation of the radical axis of two circles, $x^2 + y^2 + Dx + Ey + F = 0$ and $x^2 + y^2 + D'x + E'y + F' = 0$, is $(D - D')x + (E - E')y + (F - F') = 0$. The tangents drawn to two circles from any point of their radical axis are of equal length. If the circles intersect, the radical axis passes through their points of intersection (see p. 100).

The equation of the tangent to $x^2 + y^2 = r^2$ at (x_1, y_1) is $x_1x + y_1y = r^2$. The tangent to $x^2 + y^2 + Dx + Ey + F = 0$ at (x_1, y_1) is $x_1x + y_1y + \tfrac{1}{2}D(x + x_1) + \tfrac{1}{2}E(y + y_1) + F = 0$. The line $y = mx + b$ will be tangent to the circle $x^2 + y^2 = r^2$ if $b = r\sqrt{1 + m^2}$.

Equations of Circle in Parametric Form. It is sometimes convenient to express the co-ordinates x and y of the moving point P (Fig. 7) in terms of an auxiliary variable, called a **parameter.** Thus, if the parameter be taken as the angle u which the radius OP makes with the x-axis, then the equations of the circle in parametric form will be $x = a\cos u$; $y = a\sin u$. For every value of the parameter u, there corresponds a point (x, y) on the circle. The ordinary equation $x^2 + y^2 = a^2$ can be obtained from the parametric equations by eliminating u.

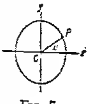

FIG. 7.

THE PARABOLA

The **parabola** (see also p. 107) is the locus of a point which moves so that its distance from a fixed line (called the **directrix**) is always equal to its distance from a fixed point F (called the **focus**). See Fig. 8. The point half-way from focus to directrix is the **vertex**, O. The line through the focus, perpendicular to the directrix, is the **principal axis**. The breadth of the curve at the focus is called the **latus rectum**, or **parameter**, $= 2p$, where p is the distance from focus to directrix. (Compare also Fig. 3, p. 174.)

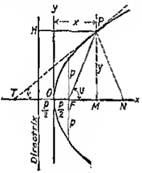

Fig. 8.

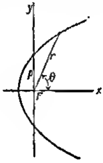

Fig. 9.

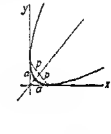

Fig. 10.

Any section of a right circular cone made by a plane parallel to a tangent plane of the cone will be a parabola.

Equation of Parabola, origin at vertex (Fig. 8): $y^2 = 2px$.

Polar Equation of Parabola, referred to F as origin and Fx as axis (Fig. 9): $r = p/(1 - \cos\theta)$.

Equation Referred to the Tangents at the ends of the latus rectum as axes (Fig. 10): $x^{1/2} + y^{1/2} = a^{1/2}$, where $a = p\sqrt{2}$.

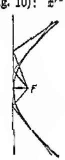

Fig. 11.

Fig. 12.

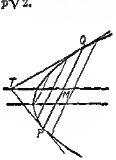

Fig. 13.

Equation of Tangent to $y^2 = 2px$ at (x_1,y_1): $y_1y = p(x + x_1)$. The line $y = mx + b$ will be tangent to $y^2 = 2px$ if $b = p/(2m)$.

The **tangent** PT at any point P bisects the angle between PF and PH (Fig. 8). A ray of light from F, reflected at P, will move off parallel to the principal axis. The **subtangent,** TM, is bisected at O. The **subnormal,** MN, is constant, and equal to p. The locus of the foot of the perpendicular from the focus on a moving tangent is the tangent at the vertex (Fig. 11). The locus of the point of intersection of perpendicular tangents is the directrix (Fig. 12). The locus of the mid-points of a set of parallel chords whose slope is m is a straight line parallel to the principal axis at a distance p/m,

the deck. The extent must be varied to suit conditions. Coaming should be at least equal to the thickness of the plate cut.

Wire-mesh screens must cover all openings into the ventilation system or cuts in bulkheads to prevent the entry and nesting of rats. Such screen should be No. 2 mesh or smaller, with wire not less than 0.064 in. diam. Screens shall be galvanized steel with a sheet-metal binding strip and be secured by machine screws or bolts spaced from 3 to 6 in. apart.

Insect screen, where required, shall be in addition to the ratproof screen and held in the same frame with it. Screen shall be No. 16 mesh with 0.014 in. diam wire.

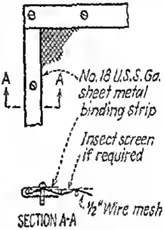

FIG. 25.—Method of holding wire mesh.

Standard cowls are the most used natural supply ventilators. They have the disadvantage that they must be trimmed to the wind; in bad weather they must be unshipped or covered. Although the air supplied depends on the wind, for design purposes it can be estimated on the basis of an 800 fpm velocity in the skirt, diameter D. Cowls up to about 15 in. can be fitted with grabs, trimmed by hand, and unshipped when necessary. Larger sizes of cowls or those not easily accessible from the deck are provided with a turning gear worked by a handle and must be trimmed away from the weather or covered as necessary.

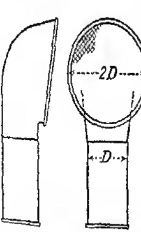

FIG. 26.—Standard cowl.

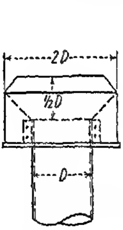

FIG. 27.—Standard mushroom.

Mushroom is a widely used ventilator head, owing to the fact that it can serve for supply or exhaust and because of its adaptability. Although both coaming and head are usually round, it can be made square, rectangular, or oval to suit conditions. The cone under the top of the mushroom is used with mechanical ventilation only. Although essentially weatherproof, a mushroom in a position exposed to seas can be fitted with a watertight damper to close down over the coaming.

quantity. These values are then tabulated on a data sheet. Set all regulating and splitter dampers in neutral position, check fan speed, and see that all conditions affecting ventilation are uniform in all compartments concerned. Doors and airports should be either all closed or all open—preferably all closed. Shutoff dampers must, of course, be wide open. After taking a full set of rough readings, balance among themselves the outlets on each individual branch. Then balance the branches one against the other, starting with those farthest from the fan and working back until the entire system is balanced proportionately. In the case of an air-conditioning system requiring adjustment down to design volume, this is accomplished after the balancing by one of three means: (1) by adjusting the fan speed, provided the required winter reduction can still be obtained below this setting; (2) by regulating the damper in the main duct; or (3) by choking down the outlets or branches individually, the last-mentioned being the least desirable. When the system is balanced, approval tests can be run and final rpm and electrical readings taken. The final test readings are made up as a report and should give location and dimensions of terminals, actual fpm, instrument correction, corrected fpm, specified cfm, and cfm delivered; also weather-opening readings—a traverse if one is taken; wet-bulb and dry-bulb temperatures; barometer; bow direction; wind direction and velocity (taken with anemometer); type of fan; motor serial number; horsepower; rated and actual rpm, volts, and amperes.

It should be noted that the weather-opening reading in cfm will frequently vary considerably from the sum of the discharge volumes. This is due to the difference in error for the different types of opening and the usual wind disturbance around the intake.

When the final tests have been accepted, the regulating and splitter dampers should be permanently locked in position by setscrew or nut and removal of handle, or by spot welding, to prevent tampering. Splitter damper rods should be either spot-welded or bent over before they are cut, to guard against their dropping into the duct if the screw should work loose.

Correction for standard air under extreme conditions may amount to about 15 percent. Generally, however, it will be less than 5 percent. It is meaningless, therefore, unless other errors are kept down to these limits. It is unnecessary in balancing unless air of widely varying temperatures is being delivered by different outlets of the same system. If, however, the tests are run for absolute values, the accuracy should be such as to warrant the air correction.

Standard air is generally taken as the weight at 70 F, 29.92 in. barometer, and 50 percent relative humidity. Since fans are rated on air of this weight, the cfm delivery will be greater with less dense air (warmer, less humid, or at lower pressure) and less with air of greater density. To obtain the volume of standard air, multiply the volume of measured air by the weight of measured air, in pounds per cubic foot, and divide by 0.07492 (the weight of 1 cu ft standard air). Properties of Air tables give the weight of dry air at any given temperature and barometric pressure, together with the increase in weight per degree wet-bulb depression at various temperatures.

Wind velocity and direction do not affect the weight of the air but should be recorded, since, if blowing directly at or away from a weather opening, it will affect the delivery of the fan.

Heat tests for temperatures maintained in various spaces under winter operation cannot be satisfactorily run unless the outside temperature is below 60 F. Likewise, cooling tests for temperature rise cannot be satis-

Gooseneck vents are made of standard pipe parts up to about 10 in. diam. In larger sizes, goosenecks and adaptations of the gooseneck are built of plate, generally with rectangular cross section. Small vents are generally fitted with covers, watertight or nontight as required. Large sizes generally have jack rods for canvas covers. Goosenecks may be used for either supply or exhaust.

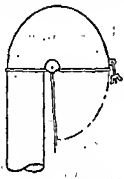

Fig. 28.—Pipe gooseneck with cover.

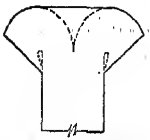

Fig. 29.—Double gooseneck.

Fig. 30.—Typical louver.

Fig. 31.—Light excluding louver

The **double gooseneck** shown in Fig. 29 is an adaptation frequently us for fan intake or discharge.

Louvers are placed in weather openings for protection against rain a spray. They are no protection against seas and should be provided wit plate or canvas cover depending on location. There are many commerc louvers suitable for shipwork. Those with movable blades are not genera heavy or tight enough to give adequate protection from seas.

The light-excluding louver finds some application on shipboard.

factorily run unless the outside air is over 70 F. For such tests thermometers should be placed so as to record temperatures of outside air, air entering the space, and representative temperatures of the air in the space. The readings on the regular duct thermometers should also be recorded. If outside temperatures are too high to permit a regular operating test, thermostatic controls may still be tested by cooling the elements with air or water of decreasing temperature and by noting the temperature at which the valve operates. Compensated controls can be checked by immersing the compensating bulb in a cooling bath of known temperature and by noting the reading on the duct thermometer following the heater being checked. Since the warm-air temperatures follow a straight-line variation as the outside air varies from 0 to 70 F, any two points, not too close together, will serve as a check. Table 7 shows a tabulation of points on the curves for a group of reheaters with compensated thermostatic controls. Intermediate points can be determined by interpolation.

Table 7. Reheater Temperatures

Outside air temperature, deg F	Temperature of air leaving reheater, deg F		
	Reheater 1	Reheater 2	Reheater 3
70	70	70	70
60	74	72	73
40	83	76	78
20	92	80	83
0	102	83	88

Natural ventilation is not generally tested quantitatively, owing to the great difficulty of getting consistent readings on outlets dependent on the wind. In cases where there is more than one outlet on a natural system, they can be roughly balanced if a steady breeze is blowing. A series of readings should be taken and averaged, testing the several outlets alternately so as to even out wind variations as much as possible.

Operating instructions covering all ventilation systems are very important in shipwork. Unlike shore installations, where the designer or contractor can be called in if something goes wrong, a ship is away from home port most of the time. Furthermore, if a vessel is sold, a complete change of operating personnel may take place thousands of miles from the building yard and the designer's office. Operation of the ventilation must, therefore, be made as simple as possible, and instructions must be as clear as possible.

Label plates should be provided to identify every fire damper, fan, fan controller, thermostatic bulb, heater, weather opening, and any other major part of the system. Also, identifying marks are frequently painted on vent ducts in engine rooms and similar locations.

A diagrammatic layout of the complete ventilation system for the vessel should be posted under glass for the use of the ship's personnel. It is generally located in or near the chief engineer's office. This should show, diagrammatically, all ductwork and equipment, the air quantity delivered by each outlet, the location of all fire dampers, and emergency control buttons. Fan identification should include system number, cfm winter and summer, and

Weather Closures. Every ventilation opening to the weather should be provided with a means of closing it against seas and weather. Openings located on the freeboard deck or other exposed positions require a cover with gasket or machine fit, which will pass a hose test for watertightness and which is of the same strength as the surrounding structure. Other openings, requiring protection from driven rain and spray but not from green seas, should have a nontight cover, *i.e.*, a plate cover without gasket, or be provided with jack rods to which a canvas cover can be lashed.

Diffusers are a commercial type of ceiling outlet, designed to deliver air at a high velocity but without objectionable drafts by means of rapid dis-

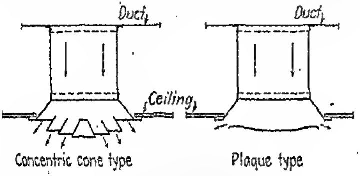

Fig. 32.—Typical diffusers.

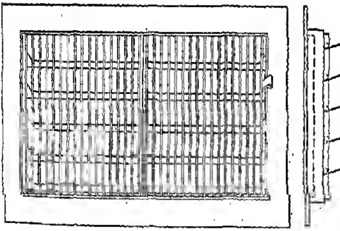

Fig. 33.—Register.

persion and mixing with the surrounding air. Diffusers are well suited for use in public rooms and staterooms. There are also types with directed air flow, suitable for group berthing spaces. The manufacturer should be consulted in the choice of sizes, but generally neck velocities of 1,000 to 1,200 fpm are acceptable. There are two basic types of diffuser: the concentric cone and the plaque types, as shown in Fig. 32. Owing to the low ceilings encountered in shipwork, diffusers are within reach of personnel and must, therefore, be of more rugged construction than is required for land installations. There are units that incorporate a diffuser and lighting fixture but, by location or construction, either lighting or ventilation efficiency is often sacrificed for the sake of appearance. The control damper can either be part of the diffuser or be located in the supply duct.

speed reduction. Heater identifying notes should cover winter cfm, temperature range, and type of control. Preferably on the same sheet with the diagram, written instructions should cover the following general items plus any additional features for a particular case, *i.e.*, air conditioning, etc.

1. *Warning.* All covers and dampers must be open before a fan is started.

2. *Emergency—Fire.* Shut off fans and close all fire closures for spaces involved. Give location of emergency stop buttons.

3. *Emergency—Weather.* Unship cowls and close weather openings as necessary to meet conditions.

4. *Summer Operation.* Fans to run at full capacity. All summer outlets to be open.

5. *Winter Operation.* Fans to run at winter operating speed, summer openings to be closed. Start heaters by first turning on main heating steam valves, then hand valves at preheaters, finally hand valves at reheaters. Include chart similar to Table 7, and explain the operation of the heaters. At the end of winter operation all hand valves shall be closed and all heaters, pipes, and traps shall be drained completely.

6. *Service and Maintenance. Filters* must be washed and recharged at regular intervals, the period depending on the vessel's service, but generally every 6 to 10 weeks. Cells should be replaced in rotation, so many every week or every two weeks depending on the total number and on the number of spare cells carried. Method of washing and charging should be described.

Motors should have grease and brushes checked, commutators and windings cleaned, once a month.

Heaters. Steam strainers at thermostatic control valves, thermometer bulbs, and thermostat elements should be cleaned at least twice a year.

7. *Fans.* A list of the systems with space served, speed reduction, and location of controls.

8. *Miscellaneous directions* for systems requiring special operation such as resistor house exhausts, emergency machine spaces, and air-conditioned spaces.

In addition to the diagram and operating instructions, it is good practice to provide additional instruction sheets to be framed in the fan rooms. These are generally small sheets covering only such of the items listed above as may apply to the equipment in the fan rooms.

Registers are a commercial type of outlet, generally bulkhead-mounted, designed to deliver air without objectionable drafts and under controlled conditions. They should have vertical vanes in the register face, which can be individually or group set to control the horizontal deflection of the air; behind these, horizontal vanes should be located, for vertical deflection and closure. The latter are controlled by a single handle (for private spaces) or by a removable key (for public spaces). The manufacturer should be consulted in choosing appropriate sizes, which are based on the following: (1) throw, or length of air travel; (2) dispersion, or vertical area covered; (3) deflection, or horizontal angle covered. A typical register is shown in Fig. 33.

Terminals. An **adjustable terminal** is a sheet-metal coned outlet which can be turned to deliver air in almost any direction. It is used principally in machinery and working spaces for supplying a controlled blast of air at high velocity (see Fig. 34).

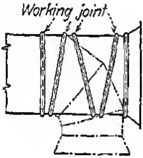

FIG. 34.—Adjustable terminal.

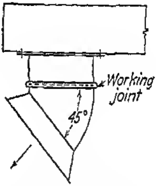

FIG. 35.—Directional terminal.

Directional terminal is a sheet-metal coned outlet which can be rotated through 360 deg to deliver air at a fixed angle. It is used principally in working spaces to supply a controlled blast of air for spot cooling (see Fig. 35).

Miscellaneous. **Dampers** and other volume-control devices are fitted for three purposes:

1. *Fire.* Dampers or closures which are easily accessible for closing off a ventilation opening, system, or part of a system, in case of emergency.

2. *Regulating.* Dampers or other devices which are used to apportion the proper volume of air to various terminals or branches when the system is being balanced and which are then permanently set in the proper position.

3. *Control or Shutoff.* Dampers that are adjustable by a crew member or passenger and permit control of the air volume supplied to a given space.

Fire dampers should be close fitting in the duct, controlled by a sturdy quadrant with bronze bearings, and of distinctive appearance. The most desirable type of fusible-link fire damper is one that may be closed manually without breaking the link. There are many types of **regulating devices** to meet various conditions. Most common are the splitter damper (see Fig. 36) which is suitable for any but very small ducts; commercial damper sets which may be locked by means of lock nut or screw; commercial vane type of volume controllers used principally with registers or grilles; and orifice plates with an opening of calculated size inserted between duct flanges.

ILLUMINATION

Based on Material Furnished by the Nela Park Department, General Electric Co.
From "Mechanical Engineers' Handbook," edited by Lionel S. Marks

REFERENCES: Moon, "The Scientific Basis of Illuminating Engineering," McGraw-Hill. Barrows, "Light, Photometry, and Illuminating Engineering," McGraw-Hill. Luckiesh and Moss, "The Science of Seeing," Van Nostrand. Forsythe, "Measurement of Radiant Energy," McGraw-Hill. Cady and Dates, "Illuminating Engineering," Wiley.

Light rays have an effective range from 3800Å to 7200Å wave length (1 Ångstrom = 10^{-7} mm) and differ from radio, infrared, ultraviolet, X-ray, gamma, and cosmic radiations only in their wave lengths.

Photometric Units

Luminous Intensity (Candles). The luminous (*i.e.*, evaluated as to its effectiveness in producing visual sensation) intensity of any radiation in a given direction is its illuminating power in that direction. It is expressed in candles, the basic unit for which is the **International candle,** and is derived from the luminous intensities of certain carbon-filament lamps maintained in the Bureau of Standards and equivalent European laboratories. In 1940, a new unit and a new standard of luminous intensity were adopted by the International Commission on Illumination (I.C.I.) based on a black body at the temperature of freezing platinum. This has a brightness of 58.6 candles per sq cm, and the new unit is defined as one-sixtieth of this brightness. The change alters but slightly the units based upon the former International candle.

Lumens. One lumen is that quantity of luminous energy included in one steradian (unit solid angle) from a uniform point source of one candle power; or, more commonly, it is the luminous flux intercepted by a surface of 1 sq ft, all points of which are 1 ft distant from a uniform point source of one candle power.

Illumination (Foot-candles). Illumination is density of luminous flux, or the amount of luminous energy per unit of area. The unit is the foot-candle and is equivalent to the density of one lumen uniformly distributed over an area of 1 sq ft; or it is the illumination at all points which are 1 ft distant from a uniform point source of one candle power. The lux is the unit used in Europe.

Brightness (Candles per Square Inch, Foot-lamberts). The brightness of an object in the direction of viewing is the luminous intensity from the object per unit of area projected along the direction of viewing. One candle per square inch is the brightness of a projected square inch of surface from which the luminous intensity is uniform and averages one candle in the direction of projection. A foot-lambert is the brightness of a perfectly diffusing surface uniformly emitting or reflecting one lumen per square foot of surface. Since no surface is a perfect diffuser, the brightness of actual surfaces will vary with the angle at which they are viewed. The brightness for each angle of viewing is expressed as the foot-lambert brightness of a similarly appearing, perfectly diffusing surface. The average brightness in foot-lamberts of any surface is therefore the product of the illumination in foot-candles and the reflection or transmission factor of the surface.

The most common type of **shutoff damper,** other than those built into a diffuser or register, is the common pull type with open, closed, and one or two intermediate positions. This type is not suitable for large ducts or with high air velocities. For the latter, a quadrant or a barrel-type with plunger is satisfactory. If a damper must be located in a concealed duct, a remote-control or extension handle should be provided.

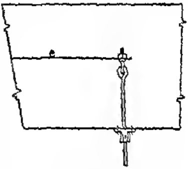

FIG. 36.—Splitter damper.

Air filters of commercial type are suitable for shipboard use, provided they are fireproof, verminproof, not subject to damage from salt water or vibration, and do not require special replacement or maintenance materials. These requirements are met by the viscous washable filter, which consists of a metal screen or frame and is periodically washed and recoated with oil. Washing and recharging equipment should be installed for the purpose. Filters are generally installed on the basis of about 800 cfm for each 20 by 20 in. filter cell.

Grease filters for use in canopies over ranges should meet about the same requirements as air filters, except that they are not oil-coated, and no washing and recharging equipment is required. They can be washed with either a steam or hot-water hose.

Blast heaters for duct installation are generally of the header type with nonferrous tubes and fins. Heaters handling straight outside air should be of the nonfreezing type, with internal steam-distributing tube construction, and be mounted with tubes vertical. Reheaters should be of single-tube construction with horizontally mounted tubes, properly pitched to provide drainage. Coils may be single or multiple row. The former are preferred owing to the lower resistance loss for a given air velocity.

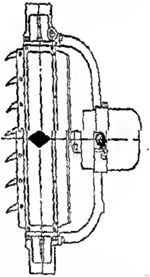

FIG. 37.—Typical unit heater.

Convectors should have a sheet-metal casing of the cabinet type, fully open at the bottom and with an outlet grille in the top only. The heating unit should be of the header type with tubes and fins to meet the heating requirements, arranged with piping connections at either end.

Unit heaters consist of a standard propeller-type fan, mounted integrally with a steam or hot-water coil, both fan and heating medium being controlled by a single switch. Adjustable horizontal vanes provide a vertical deflection of air. A typical unit heater is shown in Fig. 37.

Heating control valves should be of the modulating rather than the two-position type. Preheaters are controlled by a thermostatic bulb in the outlet duct, set for a definite temperature. Reheaters may have a room thermostat set for a definite temperature to be maintained in the space served, or a

Luminous Ratings. Light sources are rated in lumens by integrating the candle power in all directions. The **horizontal candle power** is the mean value in candles of the luminous intensity in all horizontal directions about the source. This value is but one of the mean angular candle-power values that may be determined for a source because the horizontal is but the 90 deg angular position in regard to the source axis. A candle-power distribution curve is shown in Fig. 1. The mean angular candle powers about this source are represented, *for each angular position*, by the distance of the curve from the origin in the direction being considered. The average of all candle powers is the **mean spherical candle power**, which, when multiplied by 4π (the number of steradians about a point), is numerically equal to the lumen output of the source. It is also frequently desired to know the lumens emitted in the angular zones. These are equal to the product of the zone constant (the number of steradians within the zone) and the average candle power of the zone. In practice, the candle power at the mid-elevation of each zone is used as representing the average for the zone.

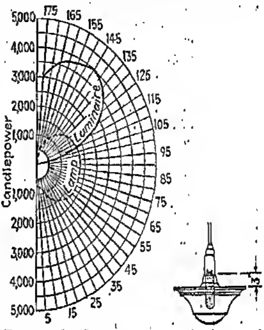

FIG. 1.—Candlepower Distribution of Lamp and Luminaire.

Equivalents and Conversion Factors.

4π lumens = the luminous flux emitted by a source of one mean spherical candle power

1 foot-candle = 10.76 lux

1 candle per sq in. = 452 foot-lamberts = 0.487 lamberts = 0.155 candles per sq cm.

The seeing task is the job to be done by the eyes. The visibility of an object depends upon its size, its brightness, its contrast with surroundings (both as to brightness and color), and the time available for seeing. The importance of time as a factor in seeing is seldom obvious and is usually given little consideration; yet, safety in the factory as well as on the highway is often closely related to it. The size, the color, and the contrast of an object can seldom be modified to make seeing easier. The remaining factor, brightness, is proportional to the illumination which is variable and which becomes the controllable factor that will determine the ultimate difficulty or ease of each visual task.

Color Vision. The visual response to a unit of radiant energy is not the same in quantity or in character for each wave length of radiation. The luminosity curve in Fig. 2 indicates the selectivity of the eye in terms of visual response per unit of energy radiated at each wave length. The curve represents the visual responses of the eye to wave lengths of the visible spectrum for brightnesses of surroundings such as are usual. The sensitivity

compensated duct thermostat set for an air temperature related to that of the outside air, as illustrated in Table 7.

The simplest control is the self-contained unit, consisting of a bulb and capillary tubing containing a fluid, the expansion of which operates a bellows in the regulating valve.

Pneumatic controls use compressed air as the power to operate the valve. These generally operate on air at 15 psi, obtained from either the ship's air supply or an independent compressor. Pneumatic control is somewhat more accurate than the self-contained unit and is capable of handling larger units, although this is seldom required in ship ventilation.

Electric controls use electric relays, solenoids, or motors to operate the valve. This is the most accurate type of control, but owing to its complication it is not so widely used as the other types described.

Regardless of the type of control used, careful adjustment is most important for proper results.

Hardware and fittings of all kinds should either be of nonferrous material or be protected against corrosion. Bolts and nuts, screws, and damper fittings should be brass, or cadmium-plated, or galvanized steel. Diffusers, registers, etc., should be cadmium- or zinc-plated, or bondorized for a priming coat finish. Working parts of registers, diffuser dampers, etc., should be of bronze. Fan and heater casings, filter frames, and other sheet-metal assemblies should be hot-dip galvanized after fabrication.

Spare parts should follow the marine provisions of the applicable rules, since ship requirements are very different than those for a land installation.

BALANCING, TESTING, AND OPERATION

No matter how well designed a ventilation system may be, it will not perform properly unless it is correctly balanced and operated. It is generally the responsibility of the ship designer or the builder: (1) to balance all ventilation systems and permanently set regulating devices; (2) to run tests that will demonstrate to the owner's satisfaction that the system is properly balanced and capable of design performance or better; (3) to furnish operating instructions for posting aboard the ship. The items of equipment most commonly used in balancing and testing ventilation systems are listed below, together with notes on their use.

Anemometer. A 4-in. rotating-vane type with range of approximately 200 to 3,000 fpm is most generally used. It is applicable to all work except where great accuracy is required near the limits of the range, or for readings outside the above range, for which cases other sizes should be used. A calibration curve comes with every instrument. The instrument should be checked periodically and recalibrated by the manufacturer as necessary.

When held in the air stream and timed for 1 min, an anemometer registers air velocity in feet per minute. It is used to measure inlet and outlet velocity readings at ventilation openings of definite area, whose smaller dimension is not less than the diameter of the rotating vanes. Readings must cover the entire area of the opening, with the face of the anemometer held parallel to the face of the opening and perpendicular to the air stream. The anemometer should be moved evenly over the opening, so that the cumulative total is a representative average for the entire area. For a very large opening or where utmost accuracy is required, a traverse should be made; *i.e.*, the total area is divided up into smaller areas, and a separate reading taken for each smaller area. The readings are then averaged after the anemometer correc-

is a maximum at approximately 5560Å wave length. If all the energy from a light source were expended at this single wave length, the resultant efficiency would be equivalent to 620 lumens per watt (lpw). The colors corresponding to various wave lengths are also indicated in Fig. 2. The eye is sensitive to any combination of wave lengths but it cannot distinguish the components. For example, a mixture of red and green lights, in neither of which there is any yellow, may produce the sensation of yellow.

Factor of Safety. The average characteristics of many eyes are used to define and determine a so-called normal one. Refractive and retinal deficiencies can usually be corrected, but nothing else can be done at the eye to increase the ease of seeing. Since actual eyes differ greatly from the average, factors of safety are necessary in illuminating engineering.

Glare. The effectiveness of the illumination on the task is reduced if there is extreme brightness within the field of view. Such brightness affects the sensitivity of the retina, reduces the size of the pupil and the brightness of the retinal image, and, hence, decreases the over-all visibility and produces discomfort and fatigue. Lighting equipment should eliminate glare as far as possible. It is recommended that no part of the light fixture or **luminaire**, within the normal field of view, be brighter than 500 foot-lamberts for exacting and prolonged tasks and 1,500 foot-lamberts for casual seeing tasks. (This range is approximately 1 to 3 candles per sq in.) The brightness of a luminaire becomes even more important if there are shiny surfaces, such as polished metal or glass desk tops, within the field of view because the luminaire will be reflected in these surfaces and will contribute brilliant reflected images.

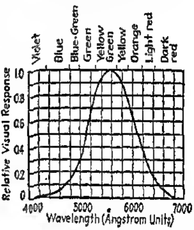

Fig. 2.—Luminosity Curve.

Light Distribution. An improper directional distribution of light is a frequent cause of glare. The illumination should be nearly the same on oblique, vertical, and horizontal surfaces; hence, shadows should not be either dense or sharply defined. Totally indirect lighting or that from large area low-brightness diffusing luminaires is preferable. With light coming from many directions, in none of which there is any extreme brightness, reflected glare is eliminated.

Some special applications require directional light distribution. In the inspection for very shallow scratches on metallic surfaces, for instance, the defects can best be seen by their specular reflection of a directional or semidirectional light source. Only the side of the scratch reflects light into the eye, the polished surface directs its reflection away from the eye making the background appear dark. When sharply directional lighting equipments as downlights, spotlights, projectors, and inspection units are used, they must be shielded and aligned so as to prevent direct and reflected glare.

Color Quality. Color quality is of varying importance. For accurate color matching, white light that has equal energy content at every visible wave length is ideal. For color discrimination, it is necessary that all wave lengths be included but that no wave length or group of them be given undue emphasis.

tion factor has been applied to each. When readings are taken, the anemom eter should be held in one hand, the hand being kept as much out of the a stream as possible, or on a stick secured to the base. In the latter case, second person should hold the stop watch, which may introduce some err unless the actions of both are coordinated. When readings are taken c weather openings exposed to the wind, a shield should be provided to reduce the effect of wind on the readings.

Velocities for various types of outlets should be determined as follows:

Wire-mesh Supply or Exhaust Openings. Figure the velocity on gross area of opening, making no allowance for screen.

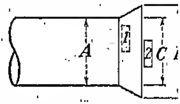

FIG. 38.—Bell or coned outle

Bell or Coned Outlet. (See Fig. 38.)

Supply. Velocity is figured on throat area A. If there is no screen, ho anemometer at position 1. If there is a screen, take readings at position over area C, which is the projection of A on the screen.

Exhaust. Velocity is figured on area B, and readings are taken in positic 2 over area B.

Registers. The manufacturer should be consulted as to the proper fact for a particular register and velocity range. In general, however, veloci should be figured on about 90 percent of the gross face area for a supply ar 100 percent for exhaust.

Diffusers. The anemometer can be used only with a test cone, or a chamb placed over diffuser. The manufacturer should be consulted as to the desig of the test device and the factors to be applied.

The anemometer is the most commonly used instrument in balancir and testing ship ventilation systems. Although, after calibration correction it may have an error up to about ± 10 percent depending on the size and ty of outlet tested, it gives reliable and consistent results and is easily handled c shipboard.

Stop Watch. A stop watch, for readings up to 1 min, is required for u with an anemometer.

Velometer. This instrument gives instantaneous readings for tl velocity of an air stream and reads directly in fpm. Calibration correctic factors are generally so small that they can be neglected in ship balancir and testing. The velometer comes with a set of jets, which are calibrat for the particular instrument and which are used only with that instrumen Regularly furnished impact jets are used for both supply and exhaust te minals. A duct jet is also desirable for taking velocity readings in duct heaters, by-passes, etc., in lieu of the more time-consuming but more accura pitot tubes. For any type of outlet, the velometer readings taken at vario points must be averaged, since the individual reading covers only a very sma area. To equal the accuracy of an anemometer and to obtain any degree consistency, considerable care should be taken with these readings. Th fact, in addition to the greater ease with which an anemometer can be handl in shipwork, limits the use of the velometer to testing outlets that cannot l measured with an anemometer and for rough checking. Principal amor these is the testing of diffusers. The diffuser manufacturer should be co sulted as to the method of test, the proper jet to use, and the factor to l applied. Six or eight readings at uniform intervals around the diffus should be taken and averaged. Care should be used to see that none of the

Specifying Foot-candles. Quality of illumination can be specified with considerable certainty but the specification of the amount of light cannot be so exact with present knowledge. The eye will function both in moonlight and in sunlight, which represents a variation in illumination from perhaps $\frac{1}{100}$ to 10,000 foot-candles—a range of a million to one. Eyes can be forced to work under inadequate and glaring lighting conditions, but the effects of the resulting eyestrain may be translated into nervousness, fatigue, indigestion, and other disorders. Since the optimum amounts of illumination are greater than those which are economically feasible, present practice is to establish minimum values for representative tasks. The eye and seeing processes are so constituted that the illumination must be doubled to achieve a significant and measurable improvement in seeing. Minimum recommended values of illumination are as follows for representative visual tasks. The values are in foot-candles of total illumination.

Industrial Interiors. *Assembly and inspection:* rough, 10; medium, 20; fine, 20 to 100; extra fine, above 100. *Machine shops:* rough bench and machine work, 10; medium bench, machine, buffing, and polishing work, rough grinding, ordinary automatic machines, 20; fine bench, machine, buffing, and polishing work, medium grinding, fine automatic machines, 50 to 100; extra fine bench and machine work, fine grinding, above 100. *Sheet metal works:* miscellaneous machines, ordinary bench work, 15; punches, presses, shears, stamps, welders, spinning, medium bench work, 20; tin-plate inspection, 50 to 100. *Woodworking:* rough sawing and bench work, 10; rough sanding, medium machine and bench work, sizing, planing, gluing, veneering, cooperage, 20; fine bench and machine work, fine sanding and finishing, 30 to 50.

Office Interiors. Corridors and stairways, 5; reception rooms, conference rooms, vaults, 10; mailrooms, file and index rooms, 20. *Desk work:* intermittent reading and writing, 20; reading blueprints and plans, 30; stenographic, reading shorthand notes, 30 to 50. *Art and drawing work:* rough sketching and drawing, 30; prolonged close work, computing, studying, drawing, drafting designing, 30 to 50. *Business machines:* (transcribing and tabulating) calculators, keypunch, bookkeeping, 50 to 100.

Supplementary Lighting. Severe visual tasks require higher levels of illumination than are practically obtainable with general lighting systems alone. It is therefore necessary to resort to supplementary lighting units. For every 10 foot-candles of supplementary lighting, at least 1 foot-candle of general illumination is needed if the ratio between task brightness and background brightness is not to become excessive and defeat the purpose of the greater illumination.

Electric Illuminants

Electric lamps convert electrical energy into light or radiant energy. The efficiency of the conversion is usually expressed in lumens per watt (lpw). As previously indicated, it is 620 lpw for a source that radiates all its energy at 5560Å wave length; it is approximately 200 lpw for a "white light" source that radiates all its energy equally at every visible wave length. These are optimum values; actual efficiencies are considerably less than these amounts.

Filament Lamps

Table 1 gives the lamp efficiencies, in lumens per watt, of past and present electric illuminants. The most important are those which contain tungsten

points fall opposite the supporting spider or other obstruction that might affect the air stream.

Sling or Hand-aspirated Psychrometer. This instrument is used to determine the wet- and dry-bulb temperature of air. These values for outside air should be recorded with every ventilation system volumetric test, in case it is desired to correct to standard air. It is also used in air-conditioning testing, in which case a psychrometric chart should be used to convert the readings to humidity values (see Fig. 1).

Barometer. The atmospheric pressure as indicated by the barometer should be recorded for volumetric tests, to permit correction to standard air if desired.

Thermometers. If a vessel's heating system is tested, straight mercury thermometers, with range of 0 to 120 deg, 32 to 180 deg, or 32 to 212 deg F are generally used in the spaces and locations required.

Pitot Tube. This is the standard instrument for measuring pressures in ventilation ducts. It consists of two concentric tubes, the outer ends of which have connections for a U-tube manometer, or differential pressure gage. Within the duct, the open end of the inner or impact tube is turned into the air stream. The outer or static tube has small holes drilled in the sides only.

If the impact tube is connected to one leg of a U-tube manometer, the other leg of the manometer being open to the atmosphere, the manometer will indicate the **impact pressure,** P_t. If the static tube is connected to one leg of a manometer, the other leg of the manometer being open to the atmosphere, the manometer will indicate the **static pressure,** P_s. If the impact tube is connected to one leg of the manometer and the static tube is simultaneously connected to the other leg of the manometer, the manometer will indicate the **velocity pressure,** P_v. The velocity pressure, measured in inches of water, is converted into velocity V, in fpm, by the following relation:

$$V = 1{,}096.2\sqrt{\frac{P_v}{d}} \text{ where } d = \text{density of air, lb per cu ft.}$$

Knowing the velocity and the sectional area A of the duct, the air volume Q, in cfm, is calculated by the relation $Q = A \times V$.

The pitot tube is used to determine the air flow Q in the main duct, the air delivery of the fan, and also the static pressure of a system or part of a system. A traverse should be made when measuring any but very small ducts. A small hole, about ½ in. diam, is provided in the duct for inserting the pitot tube at a section where fairly uniform flow is expected.

To determine the **total pressure,** P_t, of a fan, the pitot tube is inserted in the suction duct as shown in Fig. 39, and the suction impact pressure P_{it} is read, using the **impact tube.** The pitot tube is then inserted in the fan discharge duct as shown in Fig. 39, and the discharge **impact** pressure, P_{ot}, is read, using the impact tube. The total pressure, P_t, of the fan is the **sum** of the suction and discharge impact pressures, or $P_{it} + P_{ot}$.

To determine the static pressure, P_s, of a fan, the pitot tube is inserted in the fan suction duct as shown in Fig. 40, and the suction impact pressure, P_{it}, is read, using the impact tube. The pitot tube is then inserted in the fan discharge duct as shown in Fig. 40, and the discharge static pressure, P_{os}, is read, using the static tube. The static pressure, P_s, of the fan is the **sum**

Table 1. Relative Luminous Efficiencies of Electric Illuminants

	Lpw	Lumens	Life-hours
Edison's lamp	1.5		
Carbon lamps	3.4		
Gem lamps (metallized carbon filament)	4.25		
Tantalum lamps	4.8		
Osmium lamps	5.9		
Tungsten lamps (first)	7.85		
Mazda B (vacuum) lamps:			
6-watt	6.6	40	1,500
25-watt	11.0	275	750
Mazda C (gas-filled) lamps:			
40-watt	11.6	460	1,000
60-watt	13.9	830	1,000
100-watt	16.3	1,650	750
200-watt	18.5	3,700	750
300-watt	19.8	5,950	750
300-watt	19.1	5,730	1,000
500-watt	20.0	10,000	1,000
1,000-watt	21.0	21,000	1,000
1,500-watt	22.2	33,500	1,000
5,000-watt	32.7	165,000	75
Fluorescent Mazda lamps (daylight):			
15-watt	33.0*	495	2,500
20-watt	36.5*	730	2,500
30-watt	40.0*	1,200	2,500
40-watt	42.0*	1,700	2,500
Fluorescent Mazda lamps (white):			
15-watt	41.0*	615	2,500
20-watt	45.0*	900	2,500
30-watt	40.9*	1,450	2,500
40-watt	52.0*	2,100	2,500
100-watt	42.0*	4,200	2,000
30-watt green fluorescent Mazda lamp	75.0*	2,250	2,500
85-watt RF (rectified fluorescent)	47.0*	4,000	3,000
350-watt a-c Cooper-Hewitt	19.0	5,600	4,000
385-watt d-c Cooper-Hewitt	16.2	5,200	4,000
Mazda H high-intensity mercury lamps:			
100-watt (AH-4)	35.0*	3,500	1,000
250-watt (AH-2)	30.0*	7,500	2,000
400-watt (AH-1)	40.0*	16,000	2,000
1,000-watt (AH-6)	65.0*	65,000	75
180-watt sodium (NA-9)	55.5*	10,000	3,000

* Watts necessarily consumed in auxiliaries reduce these lpw values about 15 to 30 percent depending upon lamp type and size and the type of auxiliary equipment used.

filaments. These filaments radiate light by reason of their high temperature and are similar to black bodies that radiate energy in proportion to the fourth power of their absolute temperature. Tungsten is favorably selective, however, and differs from black-body radiators in that it radiates a greater proportion of the total energy in the visible spectrum.

Filaments in lamps used for illumination are made of very pure tungsten. Both tungsten and carbon are used in lamps for infrared applications. Although carbon melts at 6510 F and tungsten at only 6100 F, the latter has a much lower rate of evaporation and may be used effectively at higher operating temperatures. The efficiency of tungsten-filament lamps increases as the temperature of the filament is raised and as the wattage is increased, especially with gas filling and the larger sizes of filaments. Most filaments are wound or coiled into a helix so that their characteristics are similar to a large-diameter filament and advantage may be taken of gas-filled operation.

of the suction impact pressure, P_{it}, and the discharge static pressure, P_{os}, or $P_{it} + P_{os}$.

If no suction duct is fitted on the fan, suction readings are zero. The total pressure, P_t, of the fan $= P_{ot}$; and the static pressure, P_s, of the fan $= P_{os}$.

Differential Pressure Gage. A U-tube manometer, or other differential pressure gage, having a range of 0 to 5 in. water, is suitable for use with a

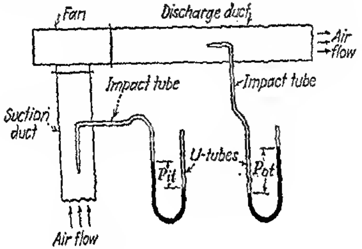

Fig. 39.—Fan total pressure.

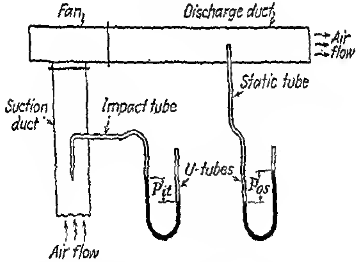

Fig. 40.—Fan static pressure.

pitot tube. If low velocities are to be measured, an inclined-tube manometer, or differential gage, with a range of 0 to 1 in. water, will permit greater accuracy in this range.

Tachometer. The fan speed should always be checked before taking air readings. A tachometer reading directly in rpm is best, but a speed counter, if timed with a stop watch, is satisfactory. An extension shaft is useful for fan openings protected by wire mesh. Speeds should never be

In some lamps, especially of lower wattage, this helix is formed into another, resulting in the so-called coiled-coil construction. This further increases the apparent diameter, shortens the apparent length of the filament, reduces the number of filament supports, and increases the efficiency. Filaments and filament mountings are adapted to specialized services such as those in which vibration or severe mechanical shock is present. Collector screens are employed in high-wattage small-bulb lamps to collect the vaporized filament particles which otherwise form a light-absorbing blackening on the bulb.

The primary purpose of the glass **bulb** as part of a lamp is to preserve the atmosphere around the filament, whether it be a nearly perfect vacuum or one of inert gases. If air or moisture is present in a lamp, the filament will be quickly oxidized and destroyed. Inert gases are introduced to reduce the evaporation of the filament. Although the gas conducts some heat away this loss is more than offset by the higher temperatures at which the filament may be operated. Bulb shapes and the type of glass used are modified for the intended service of the lamp. Softglass vacuum lamps and hardglass gas-filled lamps may be used outdoors without protection, but softglass gas-filled lamps are subject to bulb fracture if struck by rain, insects, or other moisture while hot. Hard glass is used in high wattage small-bulb lamps. Bulbs are available in clear and inside-frosted glass which has a specially acid-etched inner surface to break up the extremely directional flux from the filament without appreciable absorption. Less efficient are the coated bulbs in white and the coated or natural (transparent) colored bulbs which transmit the radiations of desired wave length and absorb all others. The directional distribution of light from a lamp may be controlled by incorporating into the bulb the desired lens or prism elements or by processing parts of the bulb with a metallic coating. Mazda projector and Sealed Beam lamps employ both of these control principles.

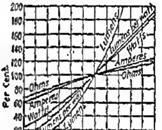

FIG. 3.—Operating Characteristic Curves for Large Gas-filled Filament Lamps.

The more common lamps have **threaded or screw bases** of the miniature, candelabra, intermediate, medium, and mogul sizes. The **bayonet base** is best represented by most automotive lamps. Those used in the headlights prior to the development of the Sealed Beam system were usually equipped with a **prefocusing** collar similar to that used on all lamps for accurate projection service. Most hard glass lamps have **bipost bases**; tubular lamps have screw, disk, or pin, depending upon the lamp design and application.

Filament-lamp Characteristics. Most lamps are designed for constant-voltage or multiple-circuit operation. Figure 3 shows the effect of other than designed voltage operation upon the characteristics of filament lamps. Although the positive resistance characteristic of the tungsten filament reduces the variation in wattage in comparison to the operating voltage, the change in lumen output of these sources is considerably greater than the wattage or voltage variation and a decrease in operating voltage results in a decreased operating efficiency.

Cost of Light. The operating voltages of filament lamps are designed as economical compromises between high operating efficiency and reasonable

taken with a tachometer on the blade side of a centrifugal or propeller fan, unless there is wire-mesh protection. There are some axial fans on which a tachometer cannot be used; it is poor practice on practically all axial fans, owing to the danger of injury and to the fact that opening the access door affects the speed.

Ammeter and Required Shunts. Electrical current readings should be taken with fan running at rated speed and full air delivery.

Voltmeter. Voltage at the fan should be read at the same time that the current is measured.

Strobotac. Speed readings on axial fans should be taken with a strobotac through an opening in the duct provided for the purpose and covered with transparent material. This is an instrument which utilized the stroboscopic principle to determine the rpm. Owing to the difficulties involved in this method, it is generally used only when a study of a fan is made. For routine regulation, the rheostat on an axial fan is usually set at a point suggested by the fan manufacturer or at rated current, on the assumption that this will give approximately rated speed.

Procedure. Before running any tests, the purpose to be achieved should be definitely ascertained and the desired accuracy decided upon. It is both wasted effort and poor engineering to apply corrections of 1 or 2 percent to one factor when other factors involved have errors of 10 or 20 percent. The accuracy required in any set of tests depends on the purpose of those tests. A study of a fan or system to determine its characteristics requires the greatest accuracy attainable; adjustment of air-conditioning systems calls for accurate balancing and air quantities within about 10 percent of specified. This accuracy is required of tests. Most straight ventilation systems require close balancing with only minor regard to the absolute air quantities.

In most shipwork, the purpose of tests is to show that the ventilating system is correctly balanced and to demonstrate its ability to function properly in service. Except for cases in which set conditions or a balance is required within a given space, this does not require that absolute air quantities be held down to the design figures. It is not sound practice, if a system is capable of delivering more than specified air volume without overloading the fan motor, to restrict it by means of regulating dampers which are permanently set, merely to show a test reading close to specifications. There are few cases in which some additional air is not advantageous under certain cooling load conditions. It is preferable, therefore, to allow a system, when permanently adjusted, to deliver its full capacity and leave it to the ship's personnel to reduce the air delivery by slowing the fan or closing the dampers provided for this purpose. In any case, if absolute air volumes are to be obtained, ship operating conditions must be maintained throughout all tests. This means giving over large sections of the ship to ventilation tests exclusively, a condition which is usually impossible during the outfitting period. It involves closing all hatches, cargo ports, air ports, doors inside and out; operating with ship's current all fans affecting a given section of the ship, and all fans in every fan room involved. Thus, since generally it is neither warranted nor feasible to adjust a straight ventilation system to specified air deliveries, the following procedure should be followed in balancing and testing such a system. Anemometer, stop watch, and velometer for diffusers will be used.

From cfm figures and areas in square feet as given on design drawings, determine the velocity in fpm for each terminal when delivering design air

lamp life which, for large gas-filled filament lamps, is inversely proportional to approximately the 13.1 power of the operating voltage (*B. of S. Paper* 502, "Characteristic Equations of Vacuum and Gas-filled Tungsten-filament Lamps)." The total cost of light in dollars per million lumen-hours depends upon the cost of the lamp delivered to the socket P (cents), the rate at which electrical energy is available R (cents per kwhr), and the light output of the source in lumens per watt E. The cost of light, in dollars per million lumen hours $= \frac{10}{E}\left(\frac{P}{WL} + R\right)$ where W is the average watts consumed by the lamp, and L is the rated life of the lamp in thousands of hours.

Vapor Lamps

During operation, the tube of a vapor lamp is filled with vapor molecules, ions, and electrons. Each gas or vapor has its own characteristics as regards color of light emission, such as blue-green for mercury, yellow for sodium, and red-orange for neon. The discharge takes place through the gas or vapor and between electrodes which are charged to differences in potential. Lamps with electrodes that are not preheated before starting are known as **cold-cathode** lamps. The electrode that has a negative potential is called the cathode; since most electrical illuminants are used in a-c circuits, each electrode is alternately a cathode and an anode. If an electrode is heated, it emits electrons more freely and these may be sufficiently accelerated by a relatively small potential to ionize the gas or vapor and establish the discharge. The electrodes of these **hot-cathode** lamps are frequently coated with oxides to provide greater electron emission at low temperatures and potentials. Coated electrodes are also used in cold-cathode lamps to provide electron emission and improve the potential gradient along the discharge.

Because of the potential gradient along the axis of a discharge, the electrodes are subject to bombardment and heating. The heated electrodes and the collision of molecules, ions, and electrons in the arc liberate additional ions and electrons in excess of the number necessary to maintain the desired current. The effect is that of a short circuit; the current tends to increase, and the result would be the destruction of the electrodes and the discharge tube were a current limiting device not used in series with these sources. Each lamp requires an auxiliary designed for its characteristics, and, in most cases, only one lamp may be operated from a single auxiliary. Because inductive devices are commonly used to limit the current in a vapor-lamp circuit, power factor becomes a consideration. The lamps, themselves, usually operate at a high power factor but a considerable reduction in this factor occurs in the auxiliary. Capacitors are generally employed with the auxiliary to improve the power factor.

Vapor lamps have long life, the length being generally determined by the life of the cathodes. These are reduced in emissivity during lamp operation, and finally the available potential is insufficient to establish the arc discharge under these conditions of reduced emission.

The **Cooper-Hewitt mercury-vapor lamp** was the first practical high-efficiency electric vapor lamp. The tube is of the cold-cathode type and depends upon an initial potential surge of several thousand volts to start. During operation the lamp remains cool and there is but slight increase in pressure. The light from these lamps is blue-green in appearance.

By increasing the operating temperature and pressure, the relative distribution of energy in the mercury spectrum is modified, and in some of the

and is called a **diameter** (Fig. 13). If M is the mid-point of a chord PQ, and if T is the point of intersection of the tangents at P and Q, then TM is parallel to the principal axis, and is bisected by the curve (Fig. 13).

To Construct a Tangent to a Given Parabola. (1) At a given point of contact, P (Fig. 14): Find T so that $OT = OM$, or $FT = FP$. Then TP is the tangent at P. Or, make $MN = p = 2(OF)$; then PN is the normal at P.

(2) From a given external point, Q (Fig. 15): With Q as center and radius QF draw circle cutting the directrix in H; draw HP parallel to principal axis; then P is required point of contact. As check, note that QP is the perpendicular bisector of FH.

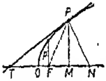

Fig. 14.

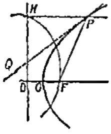

Fig. 15.

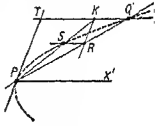

Fig. 16.

To Construct a Parabola. 1. Given Any Two Points, P and Q, the Tangent PT at One of Them, and the Direction of the Principal Axis OX. In Fig. 16, let K be a variable point on a line through Q parallel to OX. Draw KR parallel to PT (meeting PQ in R), and draw RS parallel to OX (meeting PK in S); then S is a point of the curve. Note. A line through P parallel to the principal axis bisects all chords parallel to the tangent PT.

2. Given the Vertex O and Focus F. (a) In Fig. 17 draw Oy perpendicular to OF, and slide the vertex of a right angle along Oy so that one side always passes through F; then the other side will always be a tangent to the parabola.

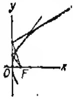

Fig. 17.

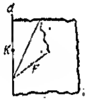

Fig. 18.

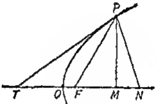

Fig. 19.

(b) Take a piece of paper (Fig. 18) with a straight edge, d, and mark a point F near the edge. Let K be a variable point of the edge, and fold the paper so that K coincides with F. The crease will be a tangent to the parabola which has focus F and directrix d.

(c) In Fig. 19, let M be a variable point of the principal axis, and lay off $MN = 2(OF) = p$. With F as center and radius FN draw a circle, cutting the perpendicular at M in P. Then P is a point of the curve, and PT and PN are the tangent and normal at P.

3. Given Two Tangents and Their Points of Contact, P and Q (Fig. 20). Divide TP and QT into any number of equal parts (here 4). Then the lines 11, 22, 33, . . . will be tangents to the parabola. This method is especially advantageous in drawing rather flat arcs.

The Radius of Curvature of $y^2 = 2px$ at a point $P = (x,y)$ is $R = (p + 2x)^{3/2}/\sqrt{p}$, or $R = p/\sin^3 v$, where v = the angle which the tangent at P makes with PF (Fig. 21). At the vertex, $R = p$. To construct the radius of curvature at any point P, lay off $PR = 2(PF)$ parallel to the principal axis, and draw RC perpendicular to the axis, meeting the normal, PN, in C. Then C is the center of curvature for the point P, and a circle about C with radius CP will coincide closely with the parabola in the neighborhood of P.

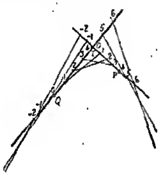

Fig. 20.

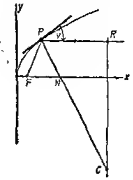

Fig. 21.

THE ELLIPSE

The ellipse (see also p. 107) has two **foci**, F and F' (Fig. 22), and two **directrices**, DH and $D'H'$. If P is any point of the curve, $PF + PF'$ is constant, $=2a$; and PF/PH (or PF'/PH') is also constant, $=e$, where e is the **eccentricity** ($e<1$). Either of these properties may be taken as the definition of the curve. The relations between e and the semi-axes a and b are as shown in Fig. 23. Thus, $b^2 = a^2(1 - e^2)$, $ae = \sqrt{a^2 - b^2}$, $e^2 = 1 - (b/a)^2$. The **semi-latus rectum** $= p = a(1 - e^2) = b^2/a$. Note that b is always less than a, except in the special case of the circle, in which $b = a$ and $e = 0$.

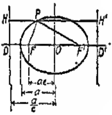

Fig. 22.

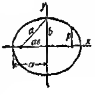

Fig. 23.

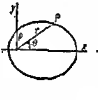

Fig. 24.

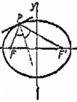

Fig. 25.

Any section of a right circular cone made by a plane which cuts all the elements of one nappe of the cone will be an ellipse; if the plane is perpendicular to the axis of the cone, the ellipse becomes a circle.

Equation of Ellipse, center as origin:

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1, \text{ or } y = \pm \frac{b}{a}\sqrt{a^2 - x^2}.$$

If $P = (x, y)$ is any point of the curve, $PF = a + ex$, $PF' = a - ex$.

Equations of the Ellipse in Parametric Form: $x = a \cos u$, $y = b \sin u$, where u is the eccentric angle of the point $P = (x,y)$. See Fig. 28.

present type H lamps, a weak continuous spectrum is obtained in addition to the distinct line spectrum. Because of the short arc length, these lamps operate at relatively low voltage and by adding a relatively small amount of argon they are also started at relatively low voltage. In some lamps the arc strikes between one of the main electrodes and a special starting electrode. The preliminary discharge then generates sufficient heat to vaporize the mercury and permit the mercury discharge to strike between the main electrodes. After several minutes' operation, the vapor pressure and the light output reach their maximums. A momentary current interruption or a sudden drop in voltage (without current interruption) will extinguish the discharge which will not strike again until the lamp has cooled and the vapor pressure has been reduced. This requires from a few seconds to 10 to 15 min depending upon the type of lamp. These lamps are comparable in size with filament sources and are adaptable to lighting equipment of similar design.

Sodium-vapor lamps are hot-cathode sources and contain neon to facilitate starting. The heat from the neon discharge vaporizes the sodium which then carries the current of the main discharge. The light is monochromatic and 5893Å in wave length. Lamps are available in 4,000, 6,000, and 10,000 lumen sizes and, although not restricted to highway and street lighting, have been used mostly in these applications. The over-all efficiency of sodium lamps and auxiliaries is approximately 45 lpw.

Fluorescent lamps are primarily low-pressure vapor lamps which make use of the ultraviolet energy from the mercury-arc discharge to activate phosphors coated on the inside bulb surface. Inside coating is essential because the glass bulb does not transmit ultraviolet radiations. Phosphors are selected which respond to radiations of 2537Å wave length as this radiation is efficiently produced by the low-pressure mercury-arc discharge. The color produced is determined by the atomic and crystalline structure of the phosphor. These lamps are hot-cathode types, a current being passed through both electrodes before they are subjected to the arc potential. They are especially efficient in the production of colored light and include one that closely approaches "daylight" at a color temperature of 6500 K.

RF lamps also contain fluorescent powders which are highly efficient in light production although not as accurately balanced for color quality as those used in Mazda F lamps. These RF lamps are a development of the former Cooper-Hewitt lamps and operate on a rectified current circuit similar to that of these earlier sources.

High-voltage Tubing. In 1915, Georges Claude patented his discovery that, for satisfactory operation, at least 23 sq in. of untreated electrode surface area are required for every ampere of current carried by high-voltage lamps of the neon type. This patent has expired and, in commercial practice, electrodes with areas of 150 to 180 sq in. per amp are used. Most high-voltage discharge tubing is of the cold-cathode type, although recent advances in the technique of using hot cathodes will probably make them of considerable importance in the future. Table 2 gives the important operating characteristics of the available sizes of these discharge tubes.

Arc Lamps

The use of **carbon electric-arc lamps** is today restricted to applications such as projection, searchlighting, and photochemical work. Arcs are efficient, rugged, and concentrated sources, the light from which can be controlled to a considerable degree in intensity, distribution, and color.

This type face is 8-point Bodoni.

The task is viewed through filters which are adjusted until the task is just discernible. At this condition, the visibility of the task may be compared with the visibility of the standard task and a specification made for the illumination necessary to make the difficulty of test and standard tasks equal. The visibility factors of size, brightness, and contrast are integrated by this meter. Since brightness is a factor of the integration, the meter evaluates the effectiveness of the illumination as well as indicates the necessary amount. It may, for instance, show that 10 foot-candles of suitable quality lighting are as effective as 100 foot-candles where the quality has been neglected.

The most frequently used foot-candle meter is the **Light Meter** which consists of a photovoltaic cell and a microammeter calibrated in foot-candles. It is a direct-reading instrument designed primarily for measuring illumination but may also be used to determine brightness, reflection factors, and transmission factors. Other portable visual instruments such as the **Macbeth illuminometer** are used in measuring candle power, illumination, and brightness; these depend upon visual observations, and accuracy depends on the observer's experience in "balancing" the brightness of screens as used in visual photometric instruments.

Several **brightness meters** are available. One of these devices contains a telescopic optical system so that readings may be taken from convenient locations. Brightness meters are visual comparison instruments and are not as easy for the layman to use as are the foot candle meters which are usually of the photoelectric type.

For d-c crater arcs, about 90 percent of the light is emitted from the crater.

Table 2. Operating Data for High-voltage Discharge Tubing*

Included is information as to the number of feet of tubing that may be operated from a *single transformer of specified characteristics.*

Transformer specifications					Color of tubing															
					Red						Blue						White or gold

In **incandescent arcs**, the tip of the positive carbon takes on the form of a crater and is heated to incandescence. When carbons of this type are used in a-c circuits, each electrode forms a small crater but the light emitted from both does not equal the emission from the single large crater in d-c operation. Forsythe ("Measurement of Radiant Energy," McGraw-Hill) rates low-intensity d-c incandescent arcs at 15 lumens per arc watt, high intensity at 29, and superhigh intensity at 32; this corresponds to 12, 23, and 25 (respectively) lumens per watt over all.

In **luminescent or flame arcs**, most of the light is produced in the arc stream just as in the mercury-vapor lamp. With carbon impregnated with certain salts, the arc stream becomes the light source and the incandescence of the electrodes is comparatively unimportant. With d-c white-flame arcs with ½ in. (⅝ in.) diameter carbons, the performance is 57 (80) lumens per watt input. Since the light is produced in the arc stream, these carbons may be used in a-c circuits with transformer ballasts instead of resistances. The over-all efficiency for these arcs is 53 lpw for ½ in. and 51.1 for ⅝ in. carbons. Carbon arcs give a concentrated high-intensity light which cannot as yet be equaled by any other source. Table 3 gives the characteristics of some carbon arcs.

SOUND AND NOISE

BY

F. V. HUNT

From "Mechanical Engineers' Handbook," edited by Lionel S. Marks

Sound is a longitudinal wave phenomenon representing the propagation of compressional waves in an elastic medium. The **velocity of propagation** V of sound waves depends on the ratio of the elastic modulus E to the density ρ of the medium, $V = \sqrt{E/\rho}$; thus $V = \sqrt{\frac{kp}{\rho}}$ for gases where k is the ratio of specific heats and p is the pressure. In air or other gases, the wave velocity is independent of the pressure, changes in density being just compensated by changes in elasticity. The velocity increases slightly with increasing relative humidity and varies directly as the square root of the absolute temperature. Thus the **normal velocity of sound in air, 1,126 fps,** increases by 0.1 percent per deg F at 68 F. The velocity of sound in liquids and solids is usually much higher than in gases (see Table 1).

Table 1. Velocity of Sound

Material	Sound vel, fps	Density, lb per cu ft	Density × velocity, lb per sq ft per sec
Aluminum	16,740	168	2.82×10^6

Hydrogen	4,165	0.00560	23.3
Water vapor, 212 F	1,328	0.0372	49.4

Approximate values from Smithsonian Tables.

The relation between **frequency** and **wave length** is, velocity = frequency × wave length. In air, at a frequency of 1,126 cycles per sec, the wave length is 1 ft.

The attentuation of sound **in transmission** through air is small. At high frequencies (above 3,000 cycles) and for low values of relative humidity, absorption in air may become large (Knudsen, *J. Acous. Soc. Am.*, 6, 1935, p. 199), but under ordinary conditions the absorption in air may be neglected. Except for absorption on reflection from material surfaces, sound waves are diminished in intensity principally in consequence of the distribution of the energy over wider areas as the sound waves are propagated from the source.

Perception of Sound

Audible Range. Sound waves having frequencies lying between 16 and 20,000 cycles per sec may be perceived as "sound" by the average young observer. Sound waves having frequencies lying below or above this range,

[b] Horizontal candle power determined directly in front of the crater on the axis of the positive carbon, except where an angle is indicated, in which cases the candle power was measured at this angle with the positive carbon axis. Candle power of crater light only, except for Suprex arcs where values are total candle power.

[c] The positive carbons in these high-intensity arcs are stationary and do not rotate.

Reflectors

Reflecting Materials. To use a reflecting material for light control, it is necessary to know the distribution of light reflected from the surface as well as the value of the reflectance. If the surface is microscopically smooth, the surface is shiny or **specular.** Polished metal and glass surfaces are specular, and the directional quality of the incident light is preserved in the reflected. If a surface is slightly irregular, the reflection from it is spread. The irregularities in depolished, etched, brushed, and stain-finished metallic, glass, and plastic surfaces render the over-all light control only moderately directional. If each element of a surface is positioned at random in regard to the general contour of the surface, the surface is **matte** and the reflection from it is **diffuse.** For any direction, the candle-power distribution and the projection of a unit area of the surface are both proportional to the cosine of the angle between the normal to the surface and the direction being considered; consequently, the ratio of the two is constant and the brightness is the same for all viewing angles. The reflection from magnesium carbonate is nearly perfectly diffused. Other surfaces of high diffusion are those of blotting paper, plaster, concrete, stone, terra cotta, matte porcelain, and matte paint.

No materials are perfectly specular or absolutely diffuse, all have distributions within these extremes. The term **spread reflection** indicates a distribution which is neither predominantly specular nor diffuse. Whereas most materials are characterized by one type of distribution or another, a few, such as shiny porcelain enamel, glazed terra cotta, structural glass, polished marble, and glass paint, have more than one. The major component is diffuse but is accompanied by a highly specular surface reflection that is [illegible] percent of the total reflectance. This latter component causes

called subaudible and supersonic waves, respectively, obey the same laws as audible sound waves. Within the audible frequency range, the ear is responsive to a wide range of intensities. In the most sensitive range, lying between 500 and 5,000 cycles, the ratio of sound intensity which the ear can tolerate to that which it can just detect is approximately 10^{12}. The minimum sound intensity that the ear can detect varies widely with the frequency. At 50 cycles, a sound, to be perceived, must be 10^6 times as intense as at a frequency of 3,000 cycles. A logarithmic scale unit, the **decibel**, is in common use for measurement and comparison of relative sound intensities. The decibel is defined by the statement: The sound intensity I_1 is N decibels higher in "intensity level" than the reference sound intensity I_0 if $N = 10 \log (I_1/I_0)$. One decibel is the minimum change in sound intensity detectable by the typical observer throughout the usual range of frequencies and intensity. The **reference intensity level** (A.S.A. Tentative Standard, 1940) is 10^{-16} watts per sq cm, and for a plane progressive sound wave in air corresponds to a variational pressure of 0.0002 dynes per sq cm. The reference intensity constitutes a sound stimulus which is approximately the minimum audible stimulus for the typical observer. The frequency and intensity range audible to the typical individual is illustrated in Fig. 1 between the extreme lower and upper curves representing, respectively, the threshold of audibility and the threshold at which sound perception merges into a feeling sensation within the ear.

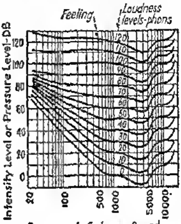

FIG. 1.—Loudness Contours.

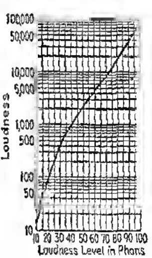

FIG. 2.—Relation between Loudness and Loudness Level.

Quality is a subjective attribute of sound by which equally loud sounds may be distinguished as different in kind. For musical tones, differences in quality arise from differences in the distribution of energy among the harmonics (overtones) of the fundamental frequency. For the unpitched sound constituting random noise, differences in quality represent differences in the distribution of energy in various parts of the acoustical spectrum. Differences in quality affect both the sensation of loudness of noise and its psychological annoyance. Shrill, high-pitched, and irregular sounds are usually judged less pleasant than low-pitched and regular sounds.

The **loudness** of a noise is not correlated simply with physically measureable attributes of the sound waves. To provide a quantitative basis for considering the subjective attribute, loudness, the term **loudness level**, in **phons**, is defined as the intensity level (decibels above standard reference level) of a pure tone having a frequency of 1,000 cycles which is judged by the

reflected images to be seen in these surfaces. Except for special effects, totally matte-surfaced materials are more satisfactory.

Table 4. Reflecting Materials

Type	Material	Per-cent reflec-tion	Type	Material	Per-cent reflec-tion

			Specular and diffuse	Porcelain enamel, glossy	60-80

Transmission. Materials that transmit light without modifying the directional distribution of the light are termed **transparent.** Clear fused quartz, clear glass, and clear plastics are of this classification. All other transmitting materials are **translucent** and, according to the distribution of light from the surfaces, are either spread or diffuse. The former are low-

Table 5. Translucent Materials

Type	Material	Per-cent trans-mis-sion	Type	*Material*	Per-cent trans-mis-sion

				Amber	40-60

diffusion materials such as frosted, configurated, and alabaster glasses, similar appearing gelatins and plastics, light-density papers, and scrim-type fabrics. The latter group includes homogeneous and cased opal glass,

typical observer to sound as loud as the sound in question. The validity of this definition rests upon the experimental observation that various observers can, with tolerable precision, agree upon the intensity of a pure tone that sounds as loud as a complex noise in question. For pure tones having frequencies other than 1,000 cycles, the "equal loudness" contours of Fig. 1 show the requisite level that will sound as loud as the reference tone of 1,000 cycles. For such pure tones, the loudness scale of Fig. 2 shows the relation between **loudness numbers** and the corresponding loudness levels, in phons. Loudness numbers obtained from this chart behave arithmetically, *i.e.*, two sounds having individual loudness numbers of 1,000 and 2,500 will, when sounded together, have a loudness corresponding to 3,500 loudness units. This chart is not reliable for complex tones having a wide spectral distribution, on account of the phenomenon of masking. The phenomenon of **masking** represents the ability of one tone present at the ear to render the ear incapable of perceiving another tone even though the second tone differs markedly in frequency from the first. The partial deafening of the ear through masking by noise affords a direct quantitative measure of the interfering effect of the noise. If the masking is measured at several frequencies throughout the audible range, the loudness of the noise may be computed; conversely, if the intensity spectrum of the noise is known, the masking at any frequency may be computed (see Fletcher and Munson, *J Acous. Soc. Am*, 9 1937 p. 1).

Noise

Noise embraces those sounds which are audibly unpleasant either by virtue of their loudness, their pitch, or their quality. Most noises are essentially unpitched and include components distributed throughout the audible frequency range. Noise usually arises from the vibration of surfaces in contact with air. When these surfaces are excited periodically, large amounts of energy may occur in particular regions of the frequency spectrum. Typical examples of noises involving regular excitation are the clash of gear teeth, the vibrations induced by unbalance in rotating machinery, the 60 cycle hum in electrical apparatus, and noise induced by the explosions in internal-combustion engines. In addition to the frequency of fundamental excitation, noises generated by such equipment contain also the resonant frequencies of the particular vibrating surfaces involved, such as the gear teeth and the motor frame. In general, small surfaces are sources of high-frequency noises, and large surfaces radiate low frequencies. Irregular excitation of vibrating surfaces, as by hammer blows or by scraping, gives rise to noises whose frequency spectrum is chiefly determined by the vibrational properties of the surfaces themselves. Hissing sounds, as of gases escaping from an orifice or originating in turbulence produced by irregularities in ducts, predominate in high frequencies and are, in general, very complex.

Noise measurements are usually carried out by means of a **sound-level meter.** This is a device involving a microphone, a vacuum-tube amplifier, and an indicating or recording instrument. The microphone is usually responsive to the sound pressure existing at the microphone. No instruments are available for objective measurements of the subjective loudness or of the sound energy flow in any sound fields except ideally simple ones. The human ear being also responsive to pressure, it is appropriate to employ a pressure-responsive instrument in estimating the objectionable amount of noise present. Bulletin Z-24.3 (1936) of the A.S.A. describes "American Tentative Standards for Sound Level Meters," and instruments meeting these specifica-

enameled glass, dense plastics, treated marble, heavier weights of paper, and treated closely woven fabrics.

Reflector Contours. Various geometric forms (Fig. 4) are employed for controlling the flux distribution from a source. In general, surfaces of revolution are used for illuminants that approach a "point source" condition and extended troughs for the linear sources. The cross section form of the surface defines the surface. All rays intercepted by a *parabolic* surface, from a point at the focus of the surface, are redirected parallel to the axis of the surface. The rays from a focus of an *elliptical* surface are redirected by the surface through the other focus of the ellipse. The rays of light from a source at the focus or center of a *circular* contour are redirected through the source. If the source is moved toward the circular contour, the resulting distribution is a combination of the characteristic distributions from parabolic and elliptical surfaces. Combinations of these basic forms may be made to obtain nearly any type of flux distribution. The distribution of light from these surfaces is not only a function of the surface contour, but also of the character of the

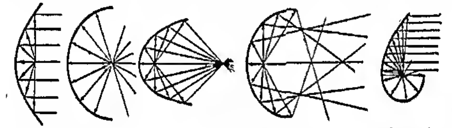

FIG. 4.—Geometric Forms Used as Reflector Contours.

surface. Accurate control is obtained only with specular surfaces; if matte surfaces are used, the contour is ineffective in controlling the light distribution although it may have a decided influence upon the total light output.

Selection of Luminaires. The luminaire, or lighting fixture, must have a distribution to provide the required amounts of horizontal, vertical, and oblique surface illumination; to reduce the harshness of shadows as much as practical; and to conform with the proportions of the room in which the installation is to be used. The brightness of the lower hemisphere should not produce direct and reflected glare. When totally or semi-indirect luminaires are used, the ceiling is the apparent source of light and may become objectionably bright when high values of illumination are provided. Combinations of general and supplementary systems are used to provide ranges of foot-candles above those available with general lighting only. In commercial interiors, downlighting is frequently used, and since it is usually designed for specific limited areas, it is considered and treated as a type of supplementary lighting.

Calculation of Illumination

Point-by-point Method of Illumination Calculation. The illumination provided by a luminaire may be calculated from a candle-power distribution curve as in Fig. 5. The calculations are based upon the "inverse square law" and are valid only for the point in consideration; the method is

tions have been produced by Electrical Research Products, Inc., General Radio Co., General Electric Co., and others. These instruments measure the total sound pressure level at the microphone, including all-frequency components, and indicate or record the result in decibels referred to the standard reference level. The **sound analyzer** is an instrument for obtaining or recording the pressure of the sound waves at each frequency. By its use, the outstanding components of a heterogeneous noise can be readily identified and can frequently be correlated with periodic excitations occurring in the apparatus producing the noise. Noise measurements serve important functions in controlling the design of new apparatus or machinery and in providing routine inspection tests for finished products. In specific applications, it is frequently observed that one portion of the frequency spectrum may be more indicative than another as a criterion of specific troubles. For these applications, the functions of the sound analyzer may be supplemented or replaced by a set of **electrical filters** which can be introduced in the amplifier of the sound-level meter and which permit the noise lying within restricted frequency ranges to be observed independently.

In making determinations of the frequency of outstanding components of a complex noise, it is convenient to employ an auxiliary sound source of variable frequency such as a **beat-frequency oscillator** connected to head telephones or a small loudspeaker. The frequency of the oscillator is varied until slow beats are observed between the variable source and the component of the noise in question.

In identifying the vibrating surface of a piece of machinery responsible for a particular component of the disturbing noise, a **vibration pickup** may be used to explore the surface of the machine. The pickup may be of the piezoelectric crystal type or the electromagnetic type and may usually be substituted for the microphone at the input of the sound-level meter. The

any point, the candle power at the point P is determined from the distribution curve. The illumination I in foot-candles at P and normal to SP at the distance D ft is $E = I/D^2$. By **Lambert's law**, the illumination on a surface is proportional to the cosine of the angle of the ray with the normal to the surface; the illumination at P, but normal to OP, $= I \cos PSO/D^2 = I \cos^3 PSO/h^2$.

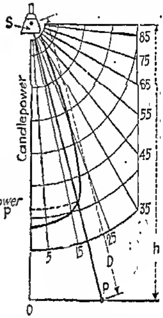

FIG. 5.—Illumination at Any Point by a Single Luminaire.

Equipment Spacing and Layout. By calculating the illumination at representative points across OP, it is possible to determine the "trend" of illumination across OP. This will establish the illumination distribution provided by a single unit. If other units are added, the illumination at each point is the sum of the components from each unit. This is represented in Fig. 6 in which the spacing of units has been made twice the mounting height and a 7 to 1 variation in illumination results. A mounting height-spacing ratio of 1 to 1, as shown in Fig. 7, gives more uniform illumination and reduces shadows. The only practical method of gaining a wider spacing distance without detrimental effect upon the illumination distribution is to increase the mounting height. For a range of ceiling heights, Table 6 gives typical spacing distances and mounting heights for direct-lighting units and suspension lengths of indirect units. Closer spacings than those in this table are often desirable either to obtain a symmetrical layout in regard to arrangement of bays, etc., or for equipments of more concentrating distribution.

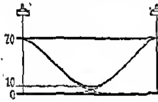

FIG. 6.—Non-uniform Illumination Resulting from Wide Spacing of Units.

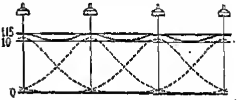

FIG. 7.—Uniform Illumination Distribution.

Lumen Method of Illumination Calculation. The point-by-point method of illumination calculations has no provisions for determining those components of the work-plane illumination not directly incident from the luminaire; the method is most valuable in determining the illumination from concentrating direct-lighting equipment such as downlights. The coefficient of utilization is the ratio of all lumens (direct or indirect) available on the work plane to those emitted by the lamps.

Large rooms use light more efficiently than small ones; in the large ones, the ratio of wall area to floor area is less and proportionately less light is

vibration amplitude is indicated directly on the sound-level-meter scale. Although not adapted to quantitative measurements, a physician's stethoscope (sometimes modified by attaching a probe rod to the center of the diaphragm) provides a sensitive detector for low-frequency vibrations.

Great care should be exercised in the maintenance of noise-measuring equipment, and attention should be given to selecting equipment that will remain unaffected by variations in temperature and humidity. When several sources of noise contribute to a complex sound, great precision is required to detect the change in the total noise produced by alteration or removal of a single component; *e.g.*, two noise sources, each capable of producing a sound level of 90 db, together produce a sound level of only 93 db. Conversely, in a composite noise produced by two noise sources, the complete quieting of one of these will produce only 3 db reduction in the measured sound level (corresponding to approximately 20 percent reduction in the subjective loudness).

Typical sound levels are shown in Table 2.

Noise Control

Control of noise is secured by following one or more of three different procedures. The primary source of the noise may be removed or altered by design changes; the transmission paths by which the sound is propagated from the source to the listener may be reduced in effectiveness; or the sound level produced at the listening position may be reduced through the process of quieting.

Source Control. Design Changes. The most effective method of controlling noise at its source is to alter the design of the offending machinery so as to reduce the vibration of external surfaces. This may involve redesigning cams to avoid sharp impacts, substitution of helical for spur gearing, provision of elastic cushioning for reciprocating parts, or the redesign of shafts or plates to shift the location of resonant frequencies. The general procedure is to seek out the vibrating surface responsible for the noise production and to attempt an alteration of design that will reduce the excitation of vibration or that will prevent the effective radiation of sound from the surface to the outside air.

Damping. When it is not possible to redesign the machinery to avoid impact or other excitation of vibrating surfaces, their vibrations may be reduced by application of lagging or other forms of viscous damping. The lagging may consist of non-hardening plastic mixtures such as putty, asphalt, or tar, which may be used as loading for cloth or felt for greater ease in handling and application and to avoid subsequent flow after application to the surface being damped. The weight of the damping layer depends on the weight and size of the vibrating panel; thus relatively rigid lagging is suitable for stiff panels having high resonant frequencies, and thicker and softer coatings are required for the suppression of low-frequency vibrations. The use of common acoustical surface absorbents for reduction of sound radiation from vibrating surfaces is not effective except for absorption of the sound after it has been radiated.

Isolation. The function of vibration isolation in quieting *machinery noises at their origin* lies in preventing the vibration of one portion of the machine from setting into vibration other portions of the machine which may be more effective radiators of sound. If the normal operation of the machine involves impacts or sudden accelerations, these force reactions should be taken up within the structure and not be allowed to reach the external

[a] Apply for rooms in which desks or benches are against the wall. Spacing for other rooms may be half the spacing between units.
[b] For illumination calculations, determine actual area which is the product of the spacing dimensions, such as $5 \times 7 = 35$ sq ft.
[c] Actual spacing dimensions of the installation.
[d] Also for semiindirect units.

redirected and absorbed by the walls. In Table 7 are **room index values** for a variety of sizes and shapes of rooms. These indices are then applied in Table 8 to determine the **coefficient of utilization** of a complete installation.

Since walls and ceilings redirect light, their reflectances influence the utilization. The distribution of flux from a luminaire and the reflectances of these room surfaces must be simultaneously considered; for it is obvious that as a luminaire directs more and more flux toward these surfaces they become increasingly important in determining the ultimate coefficient of utilization. Lighting equipment (sources, luminaires, painted surfaces) depreciates and must be maintained continually. An average maintenance factor is given for each of the representative luminaires; this factor should be modified for conditions other than average.

Spacing information as contained in Table 6 is applicable to any installation, regardless of the method of illumination calculation that is used. By using these data, those in Tables 7 and 8, and the following equation, it is possible to determine the foot-candles of illumination that will be obtained on the horizontal work plane (2½ to 3 ft above the floor) with a given size of source:

$$\text{Foot-candles} = \frac{\text{lamp lumens} \times \text{coefficient of utilization} \times \text{maintenance factor}}{\text{area of working plane in sq ft per lamp}}$$

The desired foot-candles of illumination are usually known, having been

surfaces in communication with the air, nor should they be allowed to reach a floor or mounting which would provide good radiating surfaces, or which would permit transmission of mechanical vibrations to other portions of the building with consequent radiation as noise.

Transmission Control. Isolation. If the vibrations of noisy machinery cannot be suppressed at the source, their transmission to the listener should be impeded. For the higher frequencies constituting noise, the most effective isolation method is the introduction of elastic discontinuities in the structure transmitting the noise (measured by the difference between density-velocity products as given in Table 1). The discontinuities may be obtained by the use of felt, cork, rubber, or springs in machinery mountings, or by the introduction of alternate lead and cork sheeting at masonry junctions. The isolation treatment should be applied as close to the source as possible in order to eliminate sound radiation from the structures transmitting the vibrations. Where this is not possible, the listening space itself is to be isolated. Thus **quiet rooms**, constructed especially for noise measurements, are usually built as separate structures isolated from the main building by felt, cork, or other springing.

Filtration. Some problems of noise transmission through air lend themselves to solution by methods of filtration. Typical examples are the transmission of sound in ventilating ducts and the noise production at engine exhaust pipes. In each of these cases, the steady flow of gas must not be impeded, but the alternating flow, representing sound transmission, must be effectively suppressed.

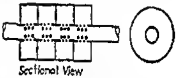

FIG. 3.—Exhaust Muffler.

For ventilating ducts, an acceptable degree of noise suppression may be obtained by lining the ducts (on at least two non-opposite walls) with an efficient sound absorbent for a distance of 10 to 15 ft from both the inlet and the outlet. Where the length of duct available is insufficient, or where additional noise suppression is required, baffles, covered with absorbing material, may be introduced in the duct. A plenum chamber, used to serve several ducts, should be lined with sound absorbents. If the air velocities are high, it may be necessary to introduce additional baffles at bends in the ducts to avoid noise production through turbulence.

Exhaust mufflers are usually modifications of the elementary low-pass acoustical filter, comprising a through tube to which closed cavities are coupled through small holes at intervals along the tube. Typical structures of this type (Fig. 3) produce little increase in back pressure and considerable attenuation of sound waves having frequencies above a cutoff frequency determined by the size of the holes and cavities. Porous packing, such as steel wool, in the side cavities or a studied irregularity in the size and spacing of the cavities will increase the uniformity of noise suppression, whereas increasing the number of side cavities and the length of the muffler will increase the amount of suppression. Baffles in the tail pipe or irregular obstructions producing devious flow paths (*e.g.*, the stone-filled pit for stationary engine exhausts) produce muffling action at the expense of appreciable increase in exhaust back pressure.

Shielding of air-borne noise must be done by sound-opaque screens large in comparison with the wave length of the sounds whose transmission they are to impede. This is seldom possible in building interiors except by utilization of building partitions as screens. Sound is transmitted through such parti-

tions principally by minute flexure of the wall as a whole in response to the incident sound pressure on the noisy side, with consequent reradiation on the quiet side. Reduction of sound transmission is obtained by increasing the mass per unit area of the partition, by constructing the partition of material having large viscosity for bending, such as Thermax, or by the use of double partitions, vibrationally isolated.

Sound-transmission loss is usually greater for high frequencies than for low and is measured by comparing the average sound level on each side of the partition under standardized conditions, as described in reports of the A.S.A. Subcommittee Z-24. Average values of transmission loss, for frequencies from 125 to 4,000 cycles, for typical partitions are shown in Table 3. In any specific case, a more exact measure of the effectiveness of an insulating partition can be obtained by direct comparison of the transmission-loss vs. frequency curve for the partition and the intensity vs. frequency curve for the noise.

Table 3. Sound-transmission Loss in Building Partitions

Wall	Thickness, in.	Weight, lb per sq ft	Transmission loss, db
Wood	0.2	0.45	18.5
Plate glass	0.25	3.2	27.0
Hollow gypsum tile, unplastered	3	11.1	27.2
Brick wall, unplastered	.....	22.0	33
Brick wall, plastered	6	46	43
Brick wall, plastered	10.5	93	49
Double wall; metal lath, ½ in. gypsum plaster, on staggered 2 × 4 in. wood studs	7.5	19.8	44
Double 3 in. hollow gypsum tile, unplastered, 3 in. air space	9	22.0	42.6
1 in. Thermax nailed over building paper to 3 in. Thermax laid up in mortar, ½ in. plaster on both sides	5	15	47
Double 2 in. solid-gypsum tile, unplastered, completely isolated structurally by separate foundations, 4 in. air space	8	20.4	59

Based on Sabine, "Acoustics and Architecture," McGraw-Hill.

In general, double partitions (including floated floor constructions) provide greater transmission loss than equally heavy concrete, masonry, or brick walls but, except for special designs, less transmission loss than equally thick masonry walls. Double walls must be constructed carefully to avoid loss of vibration isolation through mechanical bridging between the opposite surfaces. Sound-absorbing fillers (mineral wool, etc.) are usually detrimental to sound insulation if in contact with both interior surfaces, and a single bridging nail may alter significantly the insulating efficiency. For maximum effectiveness, one of the wall surfaces should be hung structurally free at all four edges with the boundary cracks sealed, with felt or asphalt compounds, against sound leakage. Through piping should be made vibrationally discontinuous by introducing canvas or metallic sylphon sections, and clearance holes at the walls should be sealed. Sound leakage through small clearance cracks contributes to the low transmission loss of ordinary doors. Special self-sealing "sound-proof" doors are required to maintain the effectiveness of an efficient sound-insulating partition.

determined by a survey of the seeing tasks to be performed. The size of source is therefore the unknown factor to be determined with the preceding equation. A lamp of approximately the output thus determined is selected from a lamp manufacturer's catalogue.

When fluorescent luminaires are used, the lumen output per luminaire is generally known so that the number of luminaires to be installed becomes

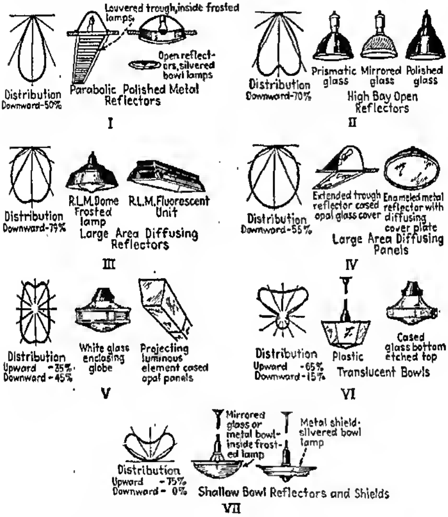

FIG. 8.—Typical Luminaires and Light Distributions.

the factor to be determined. The equation above may be written for these calculations as

$$\text{Number of luminaires to be installed} = \frac{\text{total lamp lumens required}}{\text{lamp lumens per luminaire}}$$

The layout is then planned to accommodate this number of units and in general the resulting spacings will not exceed the limits established in Table 6.

Illumination Instruments

The **Luckiesh-Moss visibility meter** appraises the difficulty of any seeing task in terms of the difficulty of reading 8-point Bodoni book monotype illuminated to 10 foot-candles.

Quieting. The sound level established in a room by a noise source is *higher than the same source would produce in free space on account of* successive reflections of sound at the walls. It is the function of **quieting** to avoid such enhancement of noise by providing a high degree of sound absorption at all interior reflecting surfaces exposed to the noise. Commercially available sound-absorbing materials may be cemented to flat surfaces or secured to wood or metal furring strips. They derive their absorbing property either from capillary porosity of the surface or from the dissipative vibration of surface layers. The effectiveness of sound absorbers varies with frequency, usually being greater for high and intermediate than for low frequencies. It may be measured by determining the **absorption coefficient,** defined as the fraction of sound energy diffusely incident on the material that is not reflected, or by determining the **specific acoustic impedance** of the material. The measured absorption coefficient is not

a property of the material alone, but depends partly on the size and mounting of the test sample and the size and shape of the test chamber; thus comparison of the coefficients for different materials should be based only on measurements made under identical conditions. Such measurements on a wide variety of materials have been made available by the Acoustical Materials Assoc. (Chicago, Ill.), although it is to be expected that the absorption coefficients effective in various practical applications may differ somewhat from the published values.

For ordinary noise quieting, the average of absorption coefficients measured at frequencies of 256, 512, 1,024, and 2,096 cycles, called the **noise-reduction coefficient**, may be used. Typical values of this coefficient for representative materials are given in Table 4. In making quantitative estimates of noise reduction, the **total sound absorption** of the room boundaries may be computed by multiplying the noise-reduction coefficient of each different *material present by the total exposed area of that material* and summing up the resulting products. The noise reduction is then given by

$$\text{Noise reduction in decibels} = 10 \log \frac{\text{total absorption after treatment}}{\text{total absorption before treatment}}$$

When the frequency spectrum of the offending noise is known, greater precision in calculation of total absorption is obtained by replacing the noise-reduction coefficient by the absorption coefficient measured at the frequency of maximum loudness level from the noise source. Subjective judgments of the loudness reduction obtained by quieting can be estimated by using the noise reduction in decibels in connection with the loudness chart of Fig. 2. Typical values of noise reduction are given in Table 5.

Table 5. Noise Reduction

Factor by which total sound absorption is increased by quieting treatment	Noise reduction, db	Percentage decrease in loudness, when original loudness level is		
		60 phons	80 phons	100 phons
2	3	18	21	23
4	6	33	38	40
6	7.8	42	46	48
10	10	50	53	57
20	13	59	62	67

Based on A.S.A. Tentative Standard (1940) for loudness reduction.

In general, the larger the area of absorbing material introduced, and the higher its noise-reduction coefficient, the more effectively the noise is reduced. No amount of quieting treatment can reduce the level of the noise received directly from the source. If full coverage of walls and ceiling is not possible, distribution of the material in several small patches is more effective than the same total area of material concentrated in one location. Similarly, the same area of material is more effective when applied to non-opposite walls and ceiling then when concentrated on either of these areas, and more effective when located near the edges and corners of a given area than when located in the center.

Polar Equation, focus as origin, axes as in Fig. 24: $r = p/(1 - e \cos\theta)$.

Equation of the Tangent at (x_1,y_1): $b^2x_1x + a^2y_1y = a^2b^2$.

The line $y = mx + k$ will be a tangent if $k = \pm\sqrt{a^2m^2 + b^2}$. The normal at any point P bisects the angle between PF and PF' (Fig. 25). The locus of the foot of the perpendicular from the focus on a moving tangent is the circle on the major axis as diameter (Fig. 26). The locus of the point of intersection of perpendicular tangents is a circle with radius $\sqrt{a^2 + b^2}$ (Fig. 27).

Fig. 29.

Ellipse as a Flattened Circle. Eccentric Angle. If the ordinates in a circle are diminished in a constant ratio, the resulting points will lie on an ellipse (Fig. 28). If Q traces the circle with uniform velocity, the corresponding point P will trace the ellipse, with varying velocity. The angle u in the figure is called the eccentric angle of the point P.

Conjugate Diameters are lines through the center, each of which bisects all the chords parallel to the other (Fig. 29). If m_1 and m_2 are the slopes, then $m_1m_2 = -b^2/a^2$. One pair of conjugate diameters are the diagonals of the rectangle circumscribing the ellipse. The eccentric angles of the ends of two conjugate diameters differ by 90 deg. Thus (Fig. 30), if CQ and CQ' are perpendicular radii in the circle, CP and CP' will be conjugate semi-diameters in the ellipse. A parallelogram formed by tangents drawn parallel to a pair of conjugate diameters has a constant area, $= 4ab$ (Fig. 31). Also, if a',b' are conjugate semi-diameters, and w the angle between them, then $a'^2 + b'^2 = a^2 + b^2$ and $a'b' = ab/\sin w$.

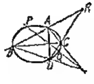

Fig. 32.

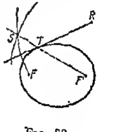

Fig. 33.

To Construct a Tangent to a Given Ellipse. (1) At a Given Point of Contact, P. Bisect the angle between the focal radii PF and PF' (Fig. 25).

(2) From a Given External Point, R. (*a*) Through R draw any two lines cutting the ellipse, one in A and B, the other in C and D (Fig. 32). Through the point of intersection of AD and BC and the point of intersection of AC and BD, draw a line cutting the ellipse in P and Q. Then P and Q are the required points of contact. (*b*) With R as a center and radius RF, draw an arc; with F' as center and radius $2a$ draw an arc, intersecting the first in S; and let SF' meet the curve in T. Then T is the point of contact (Fig. 33).

To Construct an Ellipse, Given a and b. (1) In Fig. 34, with O as center, draw circles with radii a and b (and also a third circle with radius $a + b$). Let a variable ray through O cut these circles in J, K (and S); through J and K draw parallels to the axes, meeting in P. Then P is a point of the ellipse (and SP is the normal at P).

(2) In Fig. 35, let P divide a line AB so that $PA = a$ and $PB = b$. Then if A and B slide on the axes, P will describe an ellipse.

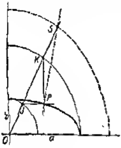

FIG. 34.

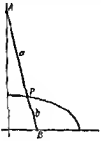

FIG. 35.

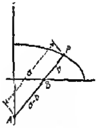

FIG. 36.

(3) In Fig. 36, let PBA be a straight line such that $PA = a$ and $PB = b$. Then if A and B slide on the axes, P will trace an ellipse. (Use a strip of paper, with the points P, B, and A marked on it.)

(4) Find the foci, F and F', by striking an arc of radius a with center at B (Fig. 37). Drive pins at F, F', and B, and adjust a loop of thread around them. Then remove the pin at B, and replace it by a pencil point; by moving the pencil so as to keep the string taut, the complete ellipse can be drawn at one sweep. Or, use a mechanical ellipsograph.

(5) and (6). Apply methods (1) and (2) of the following paragraph to the special case in which OP and OQ are perpendicular semi-axes.

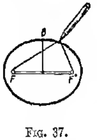

FIG. 37.

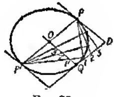

FIG. 38.

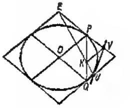

FIG. 39.

To Construct an Ellipse, Given a Pair of Conjugate Semi-diameters, OP and OQ. (1) Complete the parallelogram, as in Fig. 38. Divide QD and QO into n equal parts, $1, 2, 3, \ldots$ and $1', 2', 3', \ldots$ Connect P with $1, 2, 3, \ldots$, and P' with $1', 2', 3' \ldots$. The points of intersection of corresponding lines will be points of the ellipse.

(2) Take any point K on PQ (Fig. 39). Draw EKU, and draw KV parallel to OP. Then UV will be a tangent. By varying K along PQ as many tangents may be drawn as desired, thus "enveloping" the ellipse.

(3) Through P (Fig. 40), draw a perpendicular PT to OQ, and lay off $PR = PS = OQ$. Then if the line RPT is made to slide with one end on OR and the other on OQ, P will trace the ellipse. Further, the bisectors of the angle ROS show the directions of the principal axes, and $OR + OS = 2a$ and

speeds are slightly higher (1,500 to 4,500). The inlet-vane angle must decrease with the radius to ensure smooth entry of the water, so that it resembles a Francis turbine wheel in shape. It may be made double-suction.

3. *Mixed-flow-type Impeller.* The head developed in this type is due partly to the centrifugal and partly to the push of the vanes. The discharge is partly radial and partly axial, which is the reason for the name. The impeller is made screw-shaped (doubly curved) for the same reason as the Francis impeller. The specific speed range is usually between 4,500 and 8,000.

4. *Propeller-type Impeller.* Practically all the head developed by this type is due to the push of the vanes. The flow is entirely axial. It has the

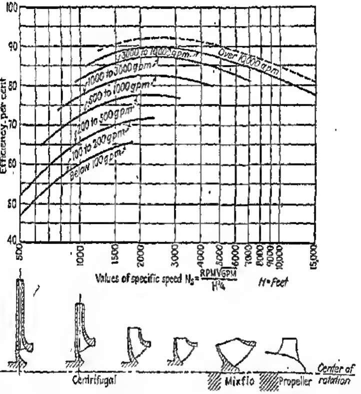

FIG. 11.—Approximate relative impeller shapes and efficiencies as related to specific speed.

highest specific speed (above 8,000) and is used for low heads (3 to 40 ft), low rpm (200 to 1,800), and large capacities.

The various types of impellers are illustrated on the lower part of Fig. 11. The upper portion of the chart gives the approximate efficiencies that can be obtained for a given specific speed and capacity. The efficiency thus obtained may be used for estimating purposes. To illustrate, it is desired to predict the brake horsepower required to drive a two-stage main condensate pump delivering 100 gpm water against a head of 200 ft while running at 3,000 rpm. The head per stage is $\frac{1}{2} \times 200$ or 100 ft, and the specific speed of each stage is $n_s = 3{,}000\sqrt{100}/100^{3/4} = 950$ (this may be found from Fig. 10). The efficiency as read from Fig. 11 is about 60 percent. The water horsepower is

MARINE PUMPS

BY

AUSTIN H. CHURCH

REFERENCES: "Standards of the Hydraulic Institute." Church, "Centrifugal Pumps and Blowers," Wiley. Pfleiderer, "Die Kreiselpumpen," Springer. Labberton, "Marine Engineering," Chap. 8, McGraw-Hill. Kristal and Annette, "Pumps," McGraw-Hill.

The three main types of marine pumps are the centrifugal, reciprocating, and rotary. Centrifugal pumps are relatively small for a given capacity and head; hence they are also cheaper, lighter, and require less floor space.

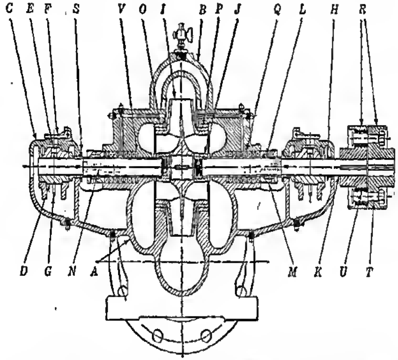

FIG. 1.—Dayton-Dowd single-stage double-suction pump. *A*, lower casing; *B*, upper casing; *C*, bearing bracket cap; *D*, bearing, lower half; *E*, bearing, upper half; *F*, oil-hole cover; *G*, oil ring; *H*, oil guard; *I*, impeller; *J*, impeller nut; *K*, shaft; *L*, shaft sleeve; *M*, gland halves; *N*, gland bolts; *O*, casing wearing ring; *P*, impeller wearing ring; *Q*, lantern ring; *R*, coupling halves; *S*, thrust collar and water slinger; *T*, coupling pins and nuts; *U*, coupling bushings; *V*, packing-box bottom.

The wear is not so great as for reciprocating pumps since the clearances are larger. They have no internal valves, are easily balanced, and deliver fluid without pulsations. Reciprocating units generally have higher efficiencies,

$\frac{wH}{550} = \frac{100 \times 8.34 \times 200}{60 \times 550} = 5.06$ (1 gal water weighs 8.34 lb), and the brake horsepower required will be

$$\frac{\text{water hp}}{\eta} = \frac{5.06}{0.6} = 8.4$$

The shape of the performance curves varies with the impeller type. This is illustrated by Fig. 12, where the head, horsepower, and efficiency are plotted on a percentage basis against the percentage flow for typical impeller types.

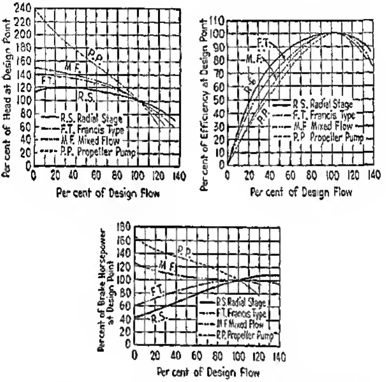

FIG. 12.—Approximate performance curves of various impeller types at partial loads.

Cavitation and Suction Head. If the suction head on a pump becomes too low, the water may vaporize and the flow will be reduced or stopped. This condition known as cavitation is usually accompanied by corrosion and erosion of the parts and noisy operation. It occurs when the absolute pressure of the water reaches the vapor pressure.

The suction head, H_{sv}, of a pump is the equivalent total head at the pump center line corrected for vapor pressure. The following four factors enter into its determination: (1) H_p is the head corresponding to the absolute pressure on the surface of the liquid from which the pump draws. This will be the atmospheric pressure if the tank is open, or the absolute pressure in the heater or closed tank from which the pump takes liquid. (2) H_z is the

particularly when handling small flows against high heads, and do not have to be primed. Rotary pumps do not have valves and are simple, compact, and cheap. They are generally used to develop high pressures (25 to 400 psi) with small flows (1 to 2,000 gpm) and are particularly effective when handling viscous fluids.

CENTRIFUGAL PUMPS

A centrifugal pump consists essentially of one or more impellers, equipped with vanes, mounted on a rotating shaft, and enclosed by a casing. Fluid enters the impeller axially near the shaft and has energy, both potential and kinetic, imparted to it by the vanes. As the fluid leaves the impeller at a relatively high velocity, it is collected in a volute or series of diffusing passages which transforms the kinetic energy to pressure. This is, of course, accompanied by a decrease in the velocity. After the conversion is accomplished, the fluid is discharged from the pump.

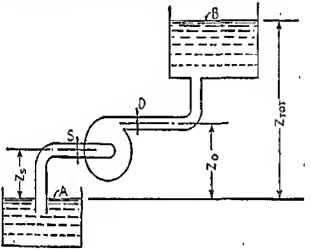

FIG. 2.—Head on a pump.

The water may enter the impeller from one side only (single-suction) or from both sides (double-suction) as illustrated in Fig. 1, which represents a typical pump of this type.

External Head Required. Before a pump can be ordered or designed, the external head against which it must operate must be found. This is made up of the sum of the friction and eddy losses occurring in the suction and discharge lines and the total increase in elevation or pressure head acquired by the liquid. Referring to Fig. 2, $H_{tot} = \Delta H_{AS} + \Delta H_{DB} + z_{tot}$. The pipe losses ΔH_{AS} and ΔH_{DB} include the friction loss plus the turbulence losses at the pipe entrance and exit, at fittings, bends, etc., while z_{tot} represents the sum of the actual lift and/or its pressure equivalent. Additional losses will occur in the pump itself (between S and D), but they will be cared for in the design and do not affect the external head required. Hence the head developed by the pump must be the difference between the total head at the center of the discharge flange and that at the center of the suction flange. Referring again to Fig. 2,

$$H_{tot} = z_D - z_S + \frac{P_D - P_S}{\gamma} + \frac{V_D^2 - V_S^2}{2g}$$

height in feet of the fluid surface above or below the impeller center line. (3) H_{vp} is the head corresponding to the vapor pressure of the liquid at the existing temperature. (4) H_f is the head lost due to friction and turbulence between the surface of the liquid and the pump suction flange.

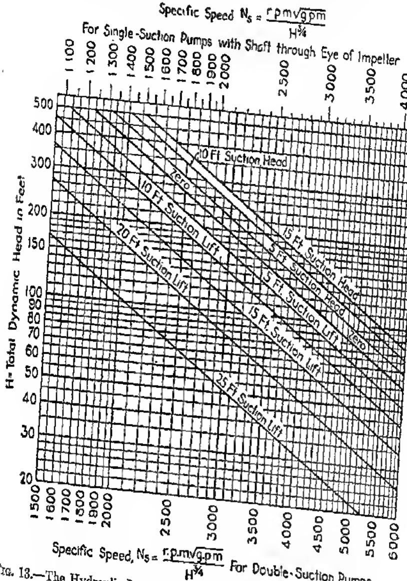

FIG. 13.—The Hydraulic Institute upper limits of specific speeds for single-stage pumps handling clear water at sea level at 85 F.

The suction head is the algebraic sum of these factors. Any term that would reduce the total suction head is negative. The vapor pressure and the loss due to friction and turbulence are always negative since they decrease the total suction head. Thus, the equation for the suction head is

$$H_{sv} = H_p \pm H_s - H_{vp} - H_f$$

where z = elevation, ft
P = pressure, lb per sq ft
γ = specific weight of liquid, lb per cu ft
V = velocity, fps
g = acceleration due to gravity = 32.2 ft per sec per sec
S and D = center lines of the suction and discharge flanges, respecti

Example. A boiler-feed pump draws water from an open heater and disc into a boiler at a pressure of 600 psi gage. The friction and eddy losses in the su amount to 2 ft head, while those in the discharge line are 4 ft. The water has weight of 59.2 lb per cu ft, and the total lift of the water is 8 ft,

$$\text{Equivalent lift of the pump, } z_{st} = \frac{600 \times 144}{59.2} + 8 = 1{,}468 \text{ ft}$$

$$\text{Total external head on the pump, } H_{ist} = 2 + 4 + 1{,}468 = 1{,}474 \text{ ft}$$

In considering the action of the water in the pump, the various ve must be taken into account. Figure 3 illustrates these velocities at t

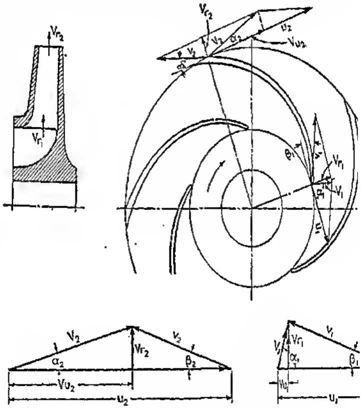

FIG. 3.—Virtual inlet and outlet velocity diagrams of pump impe

and outlet of the vane passage. The velocity of a point on the designated as u, the absolute velocity of the water (relative to the as V, and the velocity of the water relative to the impeller as v. Th between v and u corresponds to the angle of the vane and is denote the angle between u and V representing the absolute angle at wh

It may be noted that the suction velocity head, $V_{su}^2/2g$, is not included in the equation. The net suction head, H_{sv}, will appear in two forms at the suction flange, *i.e.*, as velocity and pressure heads. As the equation gives the total head and not the static pressure head, the velocity head is not included. The term H_{sv} is known as the net positive suction head over the vapor pressure and is frequently designated as NPSH.

In designing a pump installation there are two types of suction head, or NPSH, to be considered. One is the available suction head of the system, and the other is the required suction head of the pump to be placed in the system. The former is determined by the marine engineer and is based

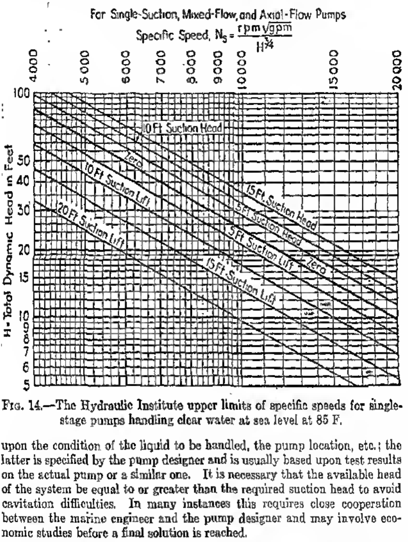

FIG. 14.—The Hydraulic Institute upper limits of specific speeds for single-stage pumps handling clear water at sea level at 85 F.

upon the condition of the liquid to be handled, the pump location, etc.; the latter is specified by the pump designer and is usually based upon test results on the actual pump or a similar one. It is necessary that the available head of the system be equal to or greater than the required suction head to avoid cavitation difficulties. In many instances this requires close cooperation between the marine engineer and the pump designer and may involve economic studies before a final solution is reached.

Example. A condensate pump draws water from a condenser in which a 27.5 in. vacuum is maintained. The friction and turbulence loss in the piping between the two is estimated to be 4 ft. If the required suction head of the pump is 12 ft and this is made equal to the available suction head of the system, what minimum height of water level in the condenser above the pump center line must be maintained? The condenser

water enters or leaves the impeller is α. The tangential component of V is V_u, while the radial component is V_r. The subscripts 1 and 2 designate the inlet and outlet edges of the vane passage, respectively.

Developed Head. If it is assumed that the water follows the vanes, the head developed by the impeller is

$$H_{vir} = \frac{u_2^2 - u_1^2}{2g} + \frac{v_1^2 - v_2^2}{2g} + \frac{V_2^2 - V_1^2}{2g}$$

where $u_2^2 - u_1^2/2g$ = head due to centrifugal action
$v_1^2 - v_2^2/2g$ = head due to the change in the relative velocity
$V_2^2 - V_1^2/2g$ = head due to the change in the absolute velocity

The first two terms represent the pressure head that is developed in the impeller, while the last term is the velocity head developed in the impeller and converted to pressure in the volute or diffuser.

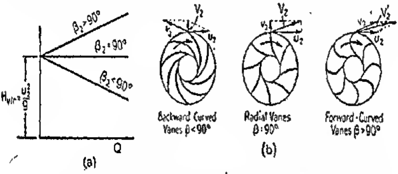

FIG. 4.—Virtual head-capacity curves and outlet velocity diagrams for various vane angles.

The foregoing equation may also be written $H_{vir} = (1/g)(u_2V_{u2} - u_1V_{u1})$. It is generally assumed that the water enters the impeller radially, hence $V_{u1} = 0$, and the latter equation reduces to $H_{vir} = u_2V_{u2}/g$.

It may be seen from these equations that the virtual head is closely linked with the vane angle at the outlet. It can be shown that this virtual head will have a straight-line relation with the flow through the pump. If the outlet angle β_2 is greater than 90 deg, the head will increase with the flow; if 90 deg, it will be constant; if less than 90 deg, it will decrease. This is illustrated by Fig. 4, which also shows the outlet velocity diagrams for various vane angles with the same radial outlet velocity component. It should be noted that the water leaves the impeller with a greater absolute outlet velocity V_2 for forward-curved vanes than for backward-curved vanes. Since the efficiency of converting velocity to pressure is related low, backward-curved vanes are always used to reduce the losses. Generally the outlet vane angle is made between 15 and 40 deg. This also aids in securing a stable characteristic curve and reduces the possibility or severity of pulsation or surging.

As the water contained in the vane passage is being accelerated, owing to the impeller rotation, it will develop a circulatory flow in the opposite direction. This flow will reduce the tangential component of the absolute outlet velocity from V_{u2} to V_{u2}' in the ratio $V_{u2}'/V_{u2} = 0.65$ to 0.75 depending

absolute pressure is 30.0 − 27.5 = 2.5 in. Hg, or 1.227 psia. This will also be the vapor pressure of the water. The corresponding specific gravity of the water is 0.9933. The

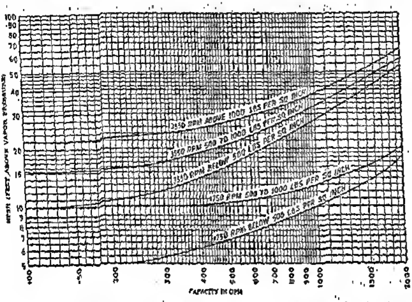

FIG. 15.—The Hydraulic Institute required net positive suction head for single-suction centrifugal hot-water pumps.

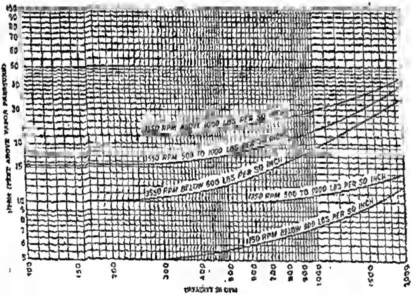

FIG. 16.—The Hydraulic Institute required net positive suction head for double-suction centrifugal hot-water pumps.

head corresponding to a given pressure in pounds per square inch is 2.31 × p/sg, hence $H_p = H_{vp} = 2.31 \times 1.227/0.9933 = 2.86$ ft. $H_f = 4$ ft. $H_{rs} = 12$ ft.

$$H_{rs} = H_p + H_z - H_{vp} - H_f$$
$$12.0 = 2.86 + H_z - 2.86 - 4.0$$

or $H_z = 16$ ft, which is the minimum height of the water level in the condenser above the pump center line.

upon the impeller type, vane shape, etc. This reduces the effective head developed by the impeller. It is further reduced by the fluid friction and turbulence losses. The former is zero at no flow and increases approximately with the square of the flow, while the latter is a minimum at the design flow and increases as the flow varies from this condition. This is illustrated in Fig. 5, the top curve being the virtual head for backward-curved vanes and the bottom the actual characteristic *curve of the pump.*

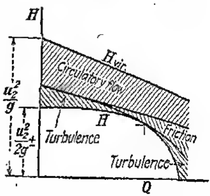

FIG. 5.—Development of the actual head-capacity curve from the virtual.

From tests it is found that, for radial-type impellers, the head at the point of maximum efficiency is between 0.8 and 1.4 of $u_2^2/2g$. This fact can be used to determine the approximate outside diameter of the impeller D_2 to develop a specified head as $u_2 = \pi D_2 n/720$. This may be written $D_2 = 1{,}840\phi\sqrt{H}/n$, where ϕ is a coefficient varying between 0.9 and 1.2, n is the rpm, and H the delivered head at the point of maximum efficiency.

When an impeller is rotated in water, power is absorbed. This is known as **disk friction.** The amount of power lost, as calculated by A. H. Gibson, is given by the equation

$$\text{hp}_{DF} = \frac{(D_2/12)^{4.83} n^{2.83}}{8.75(10)^8}$$

where n = speed, rpm
D_2 = rim diameter, in.

From this equation it may be noted that less power is absorbed if a small-diameter impeller is rotated at high speed than if a slow-speed large-diameter

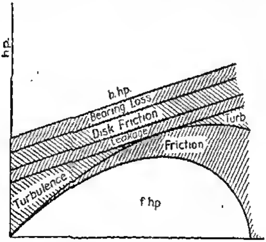

FIG. 6.—Development of actual brake-horsepower curve from the virtual.

The Hydraulic Institute has issued charts to estimate the required suction lift for pumps based upon the specific speed, total head, operating speed, etc., which are reproduced as Figs. 13 to 18. These curves are not to be taken as the very minimum required suction lift that can be obtained with special design, but they are a good guide in that they represent average results based upon the experience of a large number of pump manufacturers.

The use of the charts is simple and may be illustrated by an example.

Example. A double-suction pump operating at 3,560 rpm delivers 1,200 gpm water against a total head of 200 ft. What suction head on the pump is required for satisfactory operation?

The specific speed based upon the total flow is $n_s = \frac{n\sqrt{Q}}{H^{3/4}} = \frac{3{,}560\sqrt{1{,}200}}{200^{3/4}} = 2{,}320$ rpm, or it could be read from Fig. 10. Referring to Fig. 13, the point corresponding to a specific speed of 2,320 for double-suction pumps and a total dynamic head of 200 ft indicates about 12 ft suction lift as the safe maximum. If the same conditions were applied to a single-suction pump, the safe maximum suction condition would require at least a 7 ft positive head, *i.e.*, H_s would have to be at least $+7$ ft rather than -12 ft.

Figures 15 and 16 give the required NPSH for single- and double-suction hot-water pumps handling water with temperatures up to 212 F. For temperatures above 212 F, the NPSH as found from the figures is increased by the amount shown on Fig. 17. If the operating speed of the pump is within 25 percent of those shown on Figs. 15 and 16, the flow through the pump is corrected according to the relationship, rpm $\sqrt{\text{gpm}}$ = a constant.

Figure 18 gives the required NPSH for condensate pumps with a shaft passing through the eye of the impeller. It applies to pumps having a maximum of three stages, the lower scale representing single-suction pumps and the upper scale double-suction or a double-suction first-stage impeller. The speed-capacity relationship given above may be applied to this curve also with the same limitation.

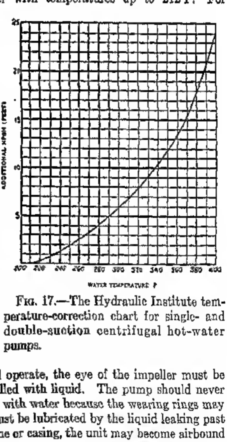

FIG. 17.—The Hydraulic Institute temperature-correction chart for single- and double-suction centrifugal hot-water pumps.

Priming. Before a pump will operate, the eye of the impeller must be submerged and the suction line filled with liquid. The pump should never be run unless the impeller is filled with water because the wearing rings may rub and seize; also the packing must be lubricated by the liquid leaking past it. If air leaks into the suction line or casing, the unit may become airbound and lose its prime, *i.e.*, cease delivery.

If water is available from an outside source, a check or foot valve may be placed in the suction line and the pump filled from this source. When the

wheel is used. Hence high-speed machines have less loss than the slow from this standpoint.

Another power loss is due to the leakage. Some of the water (2 to 10 per cent) leaving the impeller will leak past the wearing rings to the suction and must be pumped again. On multistage machines there will also be some leakage past the diaphragms between the stages.

The useful power delivered by the pump (known as **water horsepower**) is water hp $= wH/550$, where w is the weight flow in lb per sec and H is the delivered head in feet. The power required by the pump is the sum of this water horsepower, the power consumed in friction and turbulence, leakage

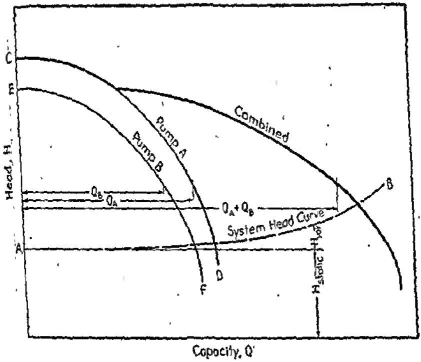

Fig. 7.—Head-capacity curves of pumps operating in parallel.

loss, disk friction, and bearing losses. Thus the brake horsepower required of the driver is made up of these components as shown in Fig. 6. The over-all efficiency of the pump for any flow is

$$\eta = \frac{\text{water hp}}{\text{bhp}}.$$

It is frequently desirable to predict the performance of a pump when operating at speeds other than that at which it is tested. The basic relationships applicable to this are $Q = Q'n'/n$; $H = H'(n'/n)^2$; bhp $=$ bhp$'(n'/n)^3$, where the primed values represent test conditions and the unprimed values the condition desired. The pump will follow these relationships over a fairly large range, with the efficiency remaining practically constant.

If the viscosity of the liquid is increased, the head will be reduced and the brake horsepower increased, thus lowering the efficiency. The exact amount of this effect is difficult to predict.

discharge line remains filled with water after the pump is stopped, this water may be used for priming by opening a by-pass valve around the pump (shown dotted in Fig. 19).

For marine installations, the priming is frequently made automatic by means of a central priming system connected to the condensate, bilge, ballast, etc., pumps that require it. The air may be removed by means of an air ejector operated by high-pressure air, steam, or water (Fig. 19), or a wet

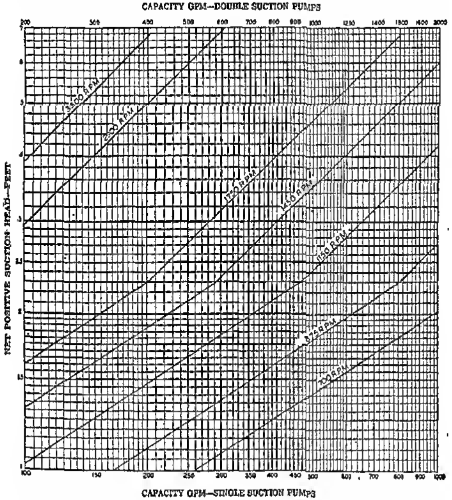

FIG. 18.—The Hydraulic Institute capacity and speed limitations for condensate pumps with a shaft through the eye of the impeller.

vacuum pump may be used. These are automatically controlled by means of a solenoid or float valve which actuates the air pump or ejector if the water level falls below a predetermined safe value.

A common type of wet vacuum pump is the Nash Hytor (Fig. 20). A rotor (5) in hydraulic balance revolves freely without contact in an elliptical casing (6) containing a liquid, usually water (4). This rotor (5) is a circular casting consisting of a series of blades that project from a cylindrical hub to form pockets or chambers. Ports are arranged at the bottom of each chamber. A cone-shaped casting containing two inlet and two outlet ports, as at (1), fits without contact into the rotor hub.

Pump Systems. It may be desirable to install several small pumps in either parallel or series to secure more flexible operation. In planning such installations, it is necessary to construct first a head-capacity curve for the system. The **system head curve** is the sum of the static head (difference in elevation and/or its pressure equivalent) plus the variable head (friction and turbulence in the pipe, bends, fittings, heaters, etc.). The former is usually constant for a given installation, whereas the latter increases approximately with the square of the flow. The resulting curve is AB in Figs. 7 and 8.

Pumps in Parallel. For pumps to operate satisfactorily in parallel they must be working on the stable part of their characteristic curves, *i.e.*, to the right of the pulsation point. The system head-capacity curve AB shown in Fig. 7 starts at H_{static} when the flow is zero and rises approximately parabolically with increased flow. Curve CD represents the head-capacity curve of pump A operating alone; the similar curve for pump B is represented by EF. Pump B will not start delivery until the delivery pressure of pump A falls below that of the shutoff head of B (point E). The combined delivery for a given head is equal to the sum of the individual capacities of the two pumps at that head. For a given combined delivery head, the capacity is divided between the pumps as noted on the figure by Q_A and Q_B. The combined characteristic curve shown on the figure is found by plotting these summations. The combined brake horsepower curve can be found by adding the brake horsepower of pump A corresponding to Q_A to that of pump B corresponding to Q_B, and plotting this at the combined flow. The efficiency curve of the combination may be determined by dividing the combined fluid horsepower, $\gamma(Q_A + Q_B)H/550$, by the corresponding combined brake horse-power (Q taken as cubic feet per second, and γ as pound per cubic foot).

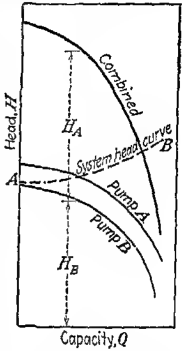

FIG. 8.—Head-capacity curves of pumps operating in series.

Pumps in Series. If two pumps are operated in series, the combined head for any flow is equal to the sum of the individual heads, as illustrated in Fig. 8. The combined brake horsepower curve may be found by adding the horsepowers given by the curves for the individual pumps. Points on the combined efficiency curve are found by dividing the combined water horsepower, $\gamma(H_A + H_B)Q/550$, by the combined brake horsepower, where the symbols have the meanings given above.

Pulsation. Under certain operating conditions, a pump will experience unstable operation and deliver, alternately, large and small quantities of fluid. This phenomenon is known as pulsation or surging and should be avoided in both design and operation, as it puts a heavy strain on the unit and system.

Starting at point A, the chambers are full of water. The water, turning with the rotor and constrained to follow the casing (6) by centrifugal force, alternately recedes from (4) and is forced back into the rotor (3) twice in a revolution. As the water recedes from the rotor (7), it draws air from the pump inlet into the cone, through the cone inlet port, and into the rotor by means of the ports in the bottom of the rotor chambers. When the water is

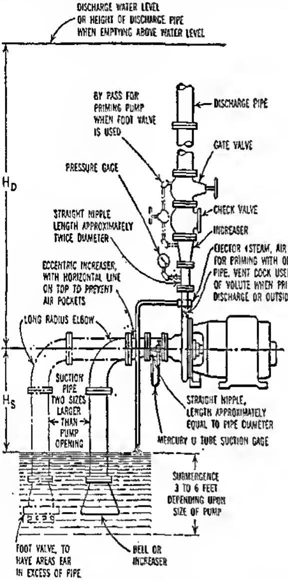

FIG. 19.—Typical pump installation and methods of priming.

forced back into the rotor by the converging casing, the air is discharged through the ports at the bottom of the rotor chambers, through the cone outlet ports, and out the pump discharge.

A small amount of seal water must constantly be supplied. Most of the water stays in the pump. Excess water is carried over with the air and is usually run to waste.

Figure 9 shows a typical characteristic curve for a pump operating at constant speed. Assume that the machine is delivering liquid to a tank or pipe system from which it is removed for use. If the demand on the system is increased, the delivered flow from the unit is also increased and the pressure in the system is reduced, *i.e.*, the operating point moves to the right toward M and the delivery pressure is decreased.

If the demand gradually decreases, the system and delivery pressure increase up to point P on the curve. For further decrease of demand, the system pressure will be higher than the delivery pressure (since the latter starts to drop off) and the fluid tends to flow back into the machine. Hence delivery from the unit stops, and the operating point jumps from P to S. If fluid is still being removed from the system, the pressure will gradually drop below that at S. When this occurs, the unit starts to deliver fluid but will not build up pressure rapidly enough to follow along the curve from S to P but instantaneously begins to deliver a flow corresponding to the pressure against it, which is that at point B. The increased flow from the pump causes the pressure to rise rapidly along the curve from B to point P, and delivery again ceases until the system pressure drops below S. This cycle repeats itself until the condition causing it is removed, *i.e.*, until the flow from the system is greater than the flow from the pump corresponding to point P.

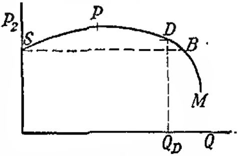

FIG. 9.—Pulsation or surging.

Point P is known as the pulsation point and is the highest point on the characteristic curve. Stable conditions prevail on the curve to the right of this point, hence it should be as far to the left as possible. As noted above, backward-curve vanes are the best from this standpoint.

Specific Speed. Specific speed is a term used to classify impellers on the basis of their performance and proportions regardless of their actual size or the speed at which they operate. Since it is a function of the impeller proportions, it is constant for a series of homologous (having the same angles and proportions) impellers or for one particular impeller operating at any speed.

It is defined as the speed in rpm at which an impeller would operate if reduced proportionately in size so as to deliver a rated capacity of one gpm against a total head of 1 ft. It is designated by the symbol n_S and found from the equation $n_S = n\sqrt{Q}/H^{3/4}$, where Q is the flow in gpm and H is the head in feet at the point of maximum efficiency.

It is not necessary to grasp the physical significance of the definition of specific speed to use it intelligently. It should be considered as a type characteristic of the impeller which specifies its general proportions and performance characteristics rather than as an rpm for special conditions of operation.

The chart of Fig. 10 may be used to find the specific speed with sufficient accuracy for practical purposes and avoids the necessity of calculating the head to the three-fourth power. The point located by plotting the total head and capacity at the point of maximum efficiency is moved parallel to the

Installation. Certain precautions should be observed in planning a pump installation and during the erection period. The suction line should be as short and straight as possible. Any elbows should have large radii. For pumps operating with suction lifts, no valves other than a foot valve should be used. The diameter of the suction line is made one or two sizes larger than the pump flange size. All these precautions ensure the maximum available suction head on the pump. When an oversized line is used, an eccentric reducer is placed between it and the pump flange to avoid high spots at which the air might collect (Fig. 19). The inlet end of the suction line should be 3 to 6 ft below the minimum water level in the sump to prevent air from being drawn into the pipe with the water.

It is desirable to have as long a length of straight pipe between the elbow and suction flange as possible to even out the flow of water as it enters the pump. The pump should be placed to secure the greatest possible suction head and yet be available for inspection and repair.

Both the suction and discharge lines should be independently supported so that no strains will be thrown on the casing which may cause distortion and rubbing. The foundation should be heavy to reduce vibrations and should be rigid enough to avoid any twisting or misalignment. When the pump is in place, it is aligned both radially and axially with the driver by means of wedges and shims so that it turns freely. If the shaft is not properly aligned, there will be vibrating and excessive wear on the bearings, packing, and wearing rings.

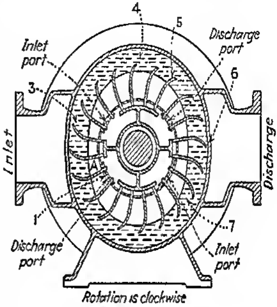

FIG. 20.—Nash-Hytor vacuum pump.

Mechanical Details. The pump shaft is usually protected by sleeves, particularly where it passes through the packing boxes, to prevent scoring and corrosion. For some applications with sea water monel metal shafts may be used, but they are more expensive than ordinary steel. The sleeves fit close to the shaft and are threaded to it as shown in the sectional drawings. The direction of the thread is counter to the direction of rotation and the sleeve is locked in place.

Both journal and antifriction bearings are used for pumps; the former are found more frequently on multistage machines, while the latter are extensively used on single-stage units.

Where the shaft enters the pump casing, packing or stuffing boxes are provided to prevent leakage. These boxes are filled with a soft packing which is compressed against the shaft by a gland which is split to facilitate replacement of the packing without removing the pump cover. For cold-water service, graphited asbestos packing is commonly employed; for hot-

dashed lines to the corresponding speed in rpm. The specific speed is read at the top of the chart directly above this final point. The procedure is illustrated by the heavy dashed lines for a pump delivering 1,200 gpm against a head of 120 ft when operating at 3,500 rpm. The specific speed is then 3,350.

For double-suction impellers the flow should be taken as one-half that handled by the pump. For multistage units the specific speed is taken as that of one stage, *i.e.*, the total head of the pump is divided by the number of stages to find the head to be used in the equation or on the chart.

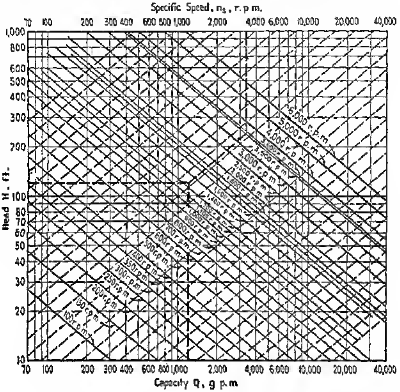

FIG. 10.—Chart for determination of specific speed.

Impeller Classification. One use of specific speed is to classify the various types of pump impellers. Each type has a range of specific speed for which it is best suited. This range is only approximate; there is no sharp line of demarcation between them.

1. *Radial-type Impeller.* The head is developed largely by the action of centrifugal force. They are used for medium and high heads (above about 150 ft). It is the conventional type of impeller and is used in practically all multistage machines. The range of specific speed is generally between 500 and 3,000. The ratio of discharge diameter to inlet eye diameter is usually in the neighborhood of 2. When larger volumes must be handled, a double-suction impeller is used.

2. *Francis-type Impeller.* For lower heads an axial-inlet, radial-discharge impeller is frequently used. For a given capacity and head this type operates at a higher speed than the conventional radial-type impeller. The specific

water service, metallic packing is frequently used. Pumps operating under suction lift have the packing divided into two parts by means of a lantern ring (item Q, Fig. 1). Water is introduced into the ring from the pump discharge line or some other pressure source to prevent air from leaking into the pump.

The impeller is usually cast in one piece and made of cast iron or bronze. It is fixed to the shaft with a light press fit, keyed, and balanced. It may be made "open" with no side plates or shrouds, "semiopen" with a shroud on the side away from the inlet only, or "enclosed" with both a front and back shroud. Open and semiopen impellers have no wearing rings, and the leakage is relatively greater unless a very closed axial clearance between the impeller and the casing is maintained. The enclosed impeller is by far the most common type and will maintain higher efficiencies for longer periods of time generally.

The wearing rings operate with close clearances to reduce the leakage and are generally made of different materials to prevent seizure in case rubbing occurs between them.

For cold-water service, the casing is usually made of cast iron for low pressures and of semisteel for discharge pressures exceeding about 100 psi. Pumps handling sea water are generally made of all bronze, *i.e.*, both the casing and impeller. Care should be taken in this case to use only one material. Although sea water has a relatively slight effect on cast iron alone or bronze alone, it will corrode the cast iron owing to electrolytic action if they are used together.

Volutes are generally used on pumps developing low heads, while diffusers are more commonly used on high-head pumps and multistage machines. If the outside diameter of the impeller is relatively large, it is not generally economical to make the casing large enough to secure sufficient conversion of the velocity head by means of a volute. Pumps having volutes generally have higher efficiencies at partial loads than diffuser pumps, since there are not so many points at which eddies may be set up.

Applications. Boiler-feed pumps must supply a dependable uninterrupted stream of water to the boilers. There must not be any cavitation; and there must be sufficient flow to prevent the water from flashing into steam while passing through the pump. To increase the suction head of high-speed units, a feed booster pump may be placed before the feed pump if a closed feed-water system is used. When operating at reduced capacity or with no flow to the boiler, a by-pass line is used to recirculate from 5 to 10 percent of the design flow back to the heater and thus prevent it from flashing into steam. For pressures below about 400 psi, the pump may be made single-stage; above this, it is usually multistage. The specific speed of the stages is relatively low, hence standard radial-type impellers are used (Fig. 21). These pumps are usually motor or steam-turbine driven at speeds of 3,500 rpm or above. Frequently they have a dual drive with a steam turbine to be used for emergency operation if the current fails. The flow through the pump is generally regulated by a water-level control which throttles the flow to the boiler.

Condensate pumps (Fig. 22) operate under a nearly constant suction and total head. The capacity is based upon the steam flow to the condenser. The impeller is either of the Francis or radial type and is usually motor-driven at a constant speed between 1,000 and 1,750 rpm, depending upon the capacity and submergence. Since the temperature of the con-

$OR - OS = 2b$. Also, if a line through P perpendicular to RS (and therefore tangent to the ellipse at P) meets the minor axis in M, a circle with M as center and MR or MS as radius will cut the major axis in the two foci.

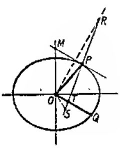

Fig. 40.

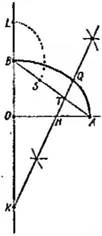

Fig. 41.

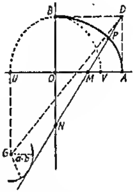

Fig. 42.

To Construct an Ellipse Approximately by Circular Arcs. [Methods (1) and (2) employ two radii, (3) and (4) employ three radii.] (1) In Fig. 41, lay off $OL = OA$ and $BS = BL = a - b$. Bisect SA in T, and draw THK perpendicular to BA. Then H is one center, with radius HA, and K is the other center, with radius KB. The junction point Q of the two arcs will fall a little outside the true ellipse.

(2) In Fig. 42, lay off $OU = OV = OB = b$. Draw UG perpendicular to the axis and DG at 45°. With G as center draw an auxiliary arc with radius

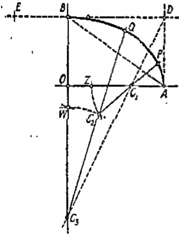

Fig. 43.

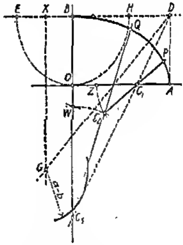

Fig. 44.

$= AV = a - b$, and through D draw DMN just touching this arc. Then M is one center (with radius MA) and N is the other center (with radius NB). The junction point P of the two arcs will be a true point of the ellipse. [E. V. Huntington.]

(3) Through D (Fig. 43) draw DC_1C_3 perpendicular to AB. Call $C_1A = r_1$ and $C_3B = r_3$. Lay off $BE = BO$ ($=b$), and on ED as diameter draw a semicircle cutting the minor axis in W; then $BW = \sqrt{ab} = r_2$. Lay off $AZ =$

BW. From C_1 with radius $C_1Z(=r_2-r_1)$, and from C_3 with radius C_3W $(=r_3-r_2)$, draw arcs intersecting in C_2. Draw C_1C_2 extended and C_2C_3 extended. Then draw in the three arcs, with centers at C_1, C_2, C_3 and radii r_1, r_2, r_3. NOTE. Since r_1 and r_3 are the radii of curvature of the ellipse at A and B, this construction gives a curve which is a little too sharp at A and a little too flat at B. A more accurate construction is the following:

(4) In Fig. 44, lay off $BE = BH = BO = b$. Through the mid-point X of BE draw XG perpendicular to the axis, and through D draw DG at an angle of 45 deg. From G as center draw an auxiliary arc with radius $= DH$ $(= a - b)$, and through D draw DC_1C_3 just touching this arc. Take C_1A as r_1 and C_3B as r_3. On DE as diameter draw a semi-circle cutting the minor axis in W, and take $BW(=\sqrt{ab})$ as r_2. Lay off $AZ = BW$. From C_1 with radius $C_1Z(=r_2-r_1)$, and from C_3 with radius $C_3W(=r_3-r_2)$, draw arcs intersecting in C_2. Then C_1, C_2, C_3 are the required centers. [E. V. Huntington.]

Radius of Curvature of Ellipse at Any Point $P = (x, y)$ **is** $R = a^4b^4(x^2/a^4 + y^2/b^4)^{3/2} = p/\sin^3 v$, where v is the angle which the tangent at P makes with PF or PF'. At end of major axis, $R = b^2/a = MA$; at end of minor axis, $R = a^2/b = NB$ (see Fig. 45). To construct the radius of curvature at any other point P (Fig. 46), draw the normal at P (by bisecting the angle between PF and PF') and let it meet the major axis in N. At N draw a perpendicular to PN meeting PF in H. At H draw a perpendicular to PH meeting PN in C. Then C is the center of curvature for the point P, and a circle about C with radius CP will coincide closely with the ellipse in the neighborhood of P. [Note. If the circle of curvature meets the ellipse in Q, then the tangent at P and the line PQ are equally inclined to the axis.]

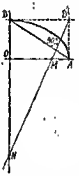

FIG. 45.

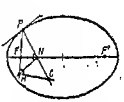

FIG. 46.

THE HYPERBOLA

The **hyperbola** (see also p. 107) has two **foci**, F and F', at distances $\pm ae$ from the center, and two **directrices**, DH and $D'H'$, at distances $\pm a/e$ from the center (Fig. 47). If P is any point of the curve, $|PF - PF'|$ is constant, $= 2a$; and PF/PH (or PF'/PH') is also constant, $= e$ (called the **eccentricity**), where $e > 1$. Either of these properties may be taken as the definition of the

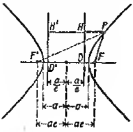

FIG. 47.

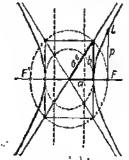

FIG. 48.

densate is close to the boiling point (at the condenser pressure), the available suction head should be carefully investigated for each installation. The pump should be kept as low as possible to reduce the suction lift, and the suction line should be made large to reduce the losses before the impeller.

Circulating pumps operate under constant head and with nearly a constant flow. The flow requirement is determined by the inlet water temperature and the amount of heat to be removed from the steam. The impeller may be either a double-suction (Fig. 1) radial, mixed-flow, or propeller type. The latter form is frequently used in marine work where space and weight are important. The head developed is usually quite low since the water in the discharge line from the condenser usually balances that

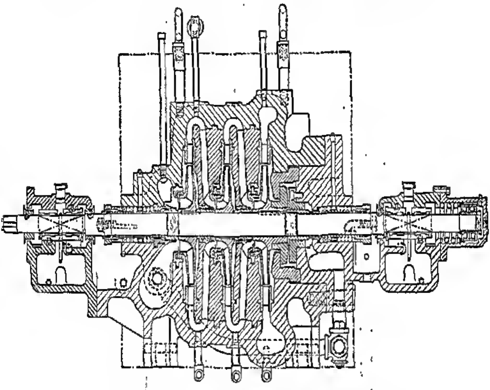

FIG. 21.—De Laval three-stage boiler-feed pump.

in the suction line. Hence the head required is only that needed to overcome the friction and eddy losses in the condenser and pipe lines. These pumps are usually motor-driven. Since the flow is large and the head low, the specific speed is high.

The chief feature of a **bilge pump** is that it must be able to pass large solids. The impeller is extra wide and has few vanes. This results in relatively low efficiencies since the liquid cannot be given much guidance. The impeller is made of cast iron and may be either semienclosed or fully enclosed (Fig. 23). The speeds range up to 1,750 rpm and the heads are low (20 to 40 ft). To prevent the packing boxes and impeller rings from being packed with dirt, provision may be made to flush them continuously with clear water. The suction lift should be low because the liberated gases tend to cause the pump to become gas bound. For this reason the inlet portion is well rounded to decrease the flow resistance, and the shaft may be vertical

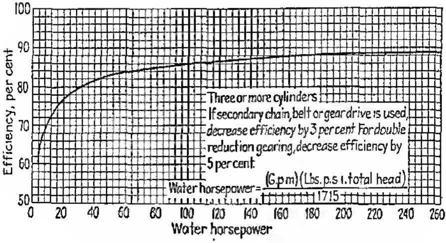

FIG. 32.—Motor-driven reciprocating-pump mechanical efficiency.

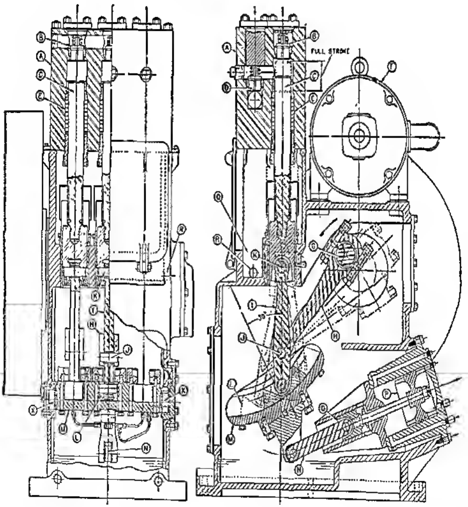

FIG. 33.—Aldrich-Groff controllable capacity pump.

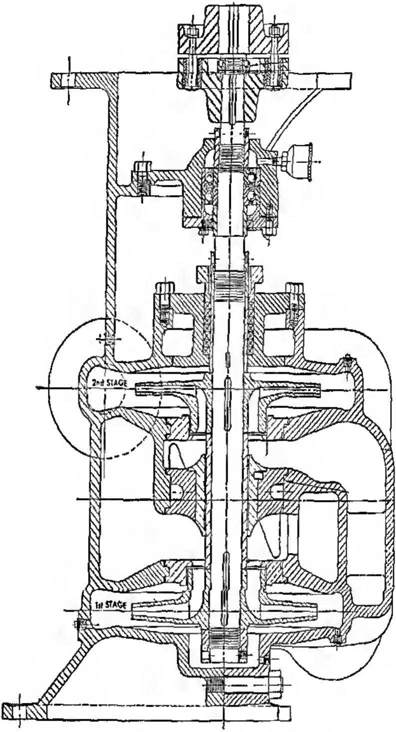

FIG. 22.—Worthington two-stage main condensate pump.

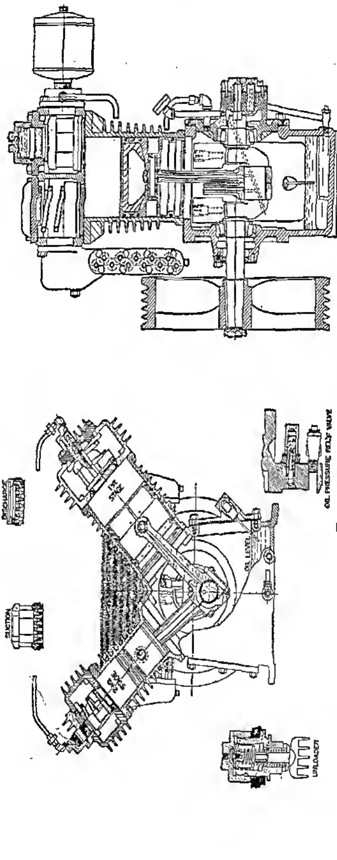

Fig. 34.—Worthington air compressor.

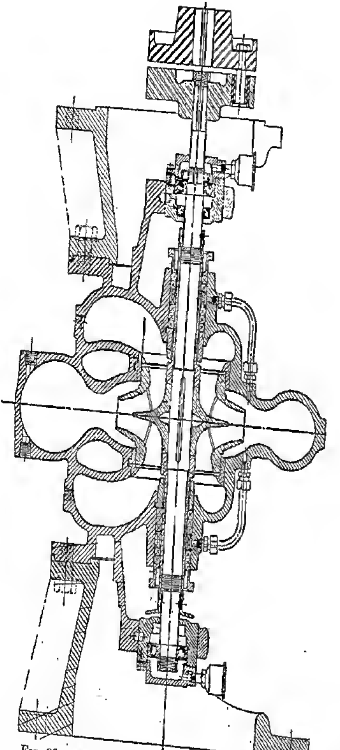

Fig. 23.—Worthington ballast and bilge pump.

may be used. The air may be cooled between the stages, either by sea water for larger sizes or by circulating air for the smaller ones. Figure 34 illustrates a motor-driven compressor of this latter type. The operation is regulated by a pressure-regulating governor. (See also page 1634.)

ROTARY PUMPS

The chief use of rotary pumps is to handle fuel and lubricating oils. They are simple, small, lightweight, and rugged. They have no valves but do require close clearances to maintain efficiency; hence they will not give satisfactory operation when used with abrasive fluids. As the leakage is reduced when the fluid handled has a high viscosity, they are particularly

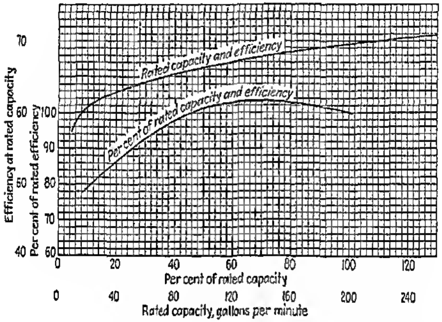

Fig. 35.—Fuel-oil booster-pump efficiencies, rotary or constant-displacement type.

adapted to that field. They are self-priming and will handle fluids containing entrained air or gas, or fluids having relatively high temperatures and low suction pressures which may cavitate. Discharge pressures of 2,000 psi and above can be obtained with capacities up to 3,500 gpm.

Only the three types most commonly used in the marine field will be considered: the screw, eccentric piston, and gear types. Figure 35 gives the approximate efficiency at rated capacities and percentage of rated efficiency for fuel-oil booster pumps of these types; Fig. 36 gives similar values for fuel-oil service pumps. These pumps frequently have a jacket for heating the viscous oil or for water cooling if desired.

Screw Pump (Fig. 37). The driven element is the center rotor which has a helical thread. Two other idler rotors mesh with it. Fluid is trapped in the spaces between the rotors and is discharged at higher pressure. The pump shown has right and left helices to balance the end thrust. The fluid enters at the ends of the rotors and is discharged at the center.

to place the impeller closer to the water level. The same type of pump is used to handle ballast.

Fire pumps may be single-stage, single- or double-suction, or as two-stage units with opposed impellers (Fig. 24). They develop a pressure of about 125 psi and are generally made in standard capacities of 500, 750, 1,000, and 1,500 gpm. **Flushing pumps** are of the same type, but generally develop

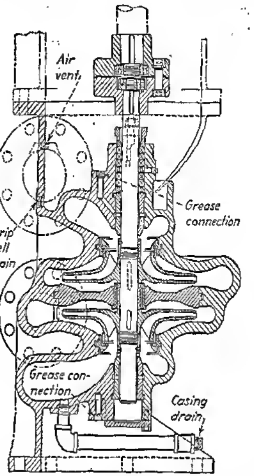

Fig. 24.—De Laval fire pump.

less pressure. Since they handle sea water, they are bronze fitted. As they are used only occasionally and the flows are not large, the efficiency is not too important. Reliability and low first cost are more essential.

RECIPROCATING PUMPS

Classification. Reciprocating pumps are divided into two general classes: direct-acting or steam pumps, and power or motor-driven pumps. The former have two cylinders in line, one steam and the other fluid. They are connected by a rod as shown in Fig. 25. The latter are frequently driven through gears or a belt, and the power is taken from a crank (Fig. 26). They are designated as simplex, duplex, triplex, etc., depending upon whether

Eccentric Piston Pump (Fig. 38). An eccentric is keyed to the driven shaft. The strap that forms the plunger has a close clearance with the pump casing. As the eccentric rotates, fluid is drawn in at the suction side and discharged above.

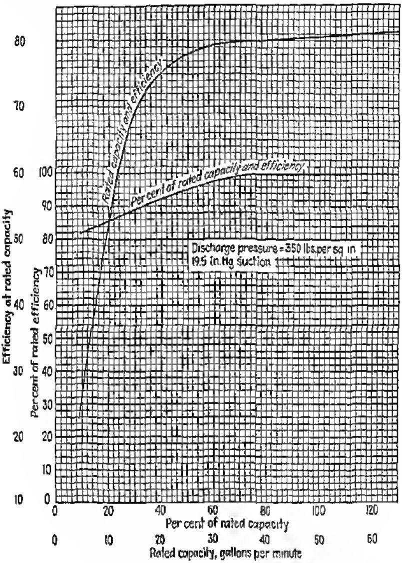

FIG. 36.—Fuel-oil service-pump efficiencies, rotary or constant-displacement type.

Gear Pump (Fig. 39). Pumps of this type consist of a pair of gears (spur or helical) enclosed in a close-fitting casing. One gear drives, while the other idles. Fluid is trapped in the space between the teeth and discharged at a higher pressure.

In designing the installation of fuel-oil pumps, it is necessary to ensure that the suction pressure is kept above the vapor pressure of the oil handled

one, two, three, etc., fluid cylinders are used. Multicylinder pumps will have a more even torque fluctuation than the single-cylinder type. The pump piston may be either single- or double-acting. For marine work they are generally mounted vertically to save floor space.

Mechanical Details. The steam end of direct-acting pumps generally has a cast-iron liner inserted in a steel cylinder, while the water end usually has a bronze liner fitted to a cast-iron cylinder. The rods are made of stainless steel when fresh water is handled, or of monel metal for salt water.

The valve on the steam end of direct-acting pumps is generally of the conventional *D* slide-valve or piston type, and usually operates without cutoff, *i.e.*, there is no expansion of the steam in the cylinder. As the exhaust steam is frequently used for feed-water heating, this practice is not too wasteful

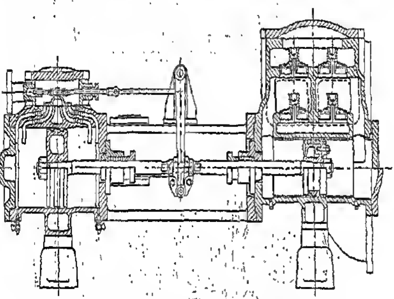

Fig. 25.—Worthington steam-driven reciprocating pump.

and it ensures dependable action. The valve is actuated by the piston rod, shown in Fig. 25.

For the moderate pressures usual in marine work, the water valves are usually of the spring-loaded disk or poppet type. The valve seat is fixed to the frame either by threads or by a slight taper. The disks are made of rubber for low-pressure cold water; while for low-pressure hot water and for lubricating- or fuel-oil services, metal disks are employed. For all high-pressure service the disks are generally made of fabric impregnated with phenolic-base gum.

Design Factors. The size of direct-acting pumps is specified by three numbers in the following order: steam cylinder diameter, water cylinder diameter, and stroke, all in inches.

The leakage past the piston or plunger, the valves, and the packing is known as slip and generally accounts to 1 to 5 percent, depending upon the pump type, clearances, etc.

The **efficiency** of reciprocating pumps is the ratio of the fluid horsepower to the indicated steam horsepower. The water hp = gpm × head, in psi/1,715;

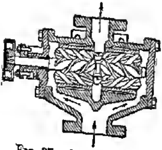

FIG. 37.—Screw pump.

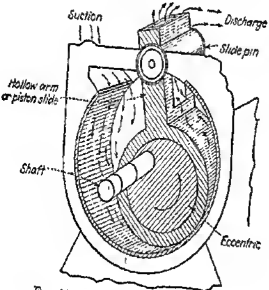

FIG. 38.—Rotating-plunger pump.

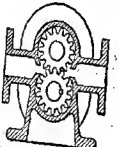

FIG. 39.—Gear pump.

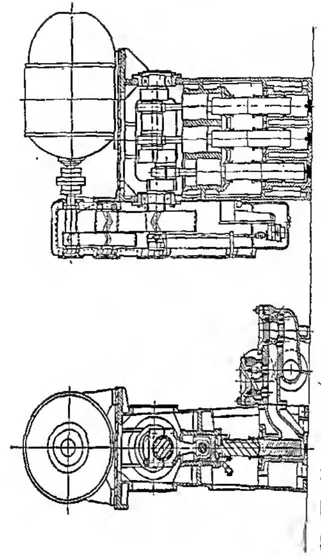

FIG. 26.—Worthington motor-driven reciprocating power pump.

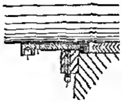

to prevent cavitation and vapor binding, which would reduce the pump capacity and result in generally unsatisfactory operation. Figure 40 gives the vapor pressure of various oils as a function of the temperature. The

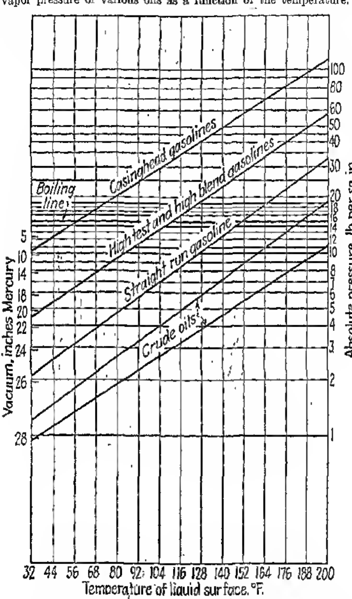

FIG. 40.—Vapor pressure chart for various fuels.

absolute suction pressure should be a safe margin above the values given on the chart for satisfactory operation.

GENERAL

The approximate discharge pressures in pounds per square inch of marine pumps are given in the accompanying table. These values may be used for preliminary estimates of heat balance and costs, but they will of course vary with different ships.

d the indicated steam horsepower = $pLAn/198{,}000$, where p is the steam essure in pounds per square inch, A the cylinder area in square inches, L the roke in inches, and n the *rpm* or number of double strokes per minute. pproximate efficiencies which may be used for estimating purposes may be ken from Fig. 27.

The rubbing speed of a pump in feet per minute is $V = Ln/6$, where the mbols have the meanings given above. Conservative operating speeds, nown as **basic speeds,** for direct-acting pumps handling cold water or quids of a viscosity not over 250 SSU are given in Fig. 28 issued by the Iydraulic Institute, and apply to both simplex and duplex pumps. For igher temperatures or viscosities, the speed is reduced in accordance with 'ig. 29. These charts represent average commercial practice rather than he values to be used for specially designed pumps.

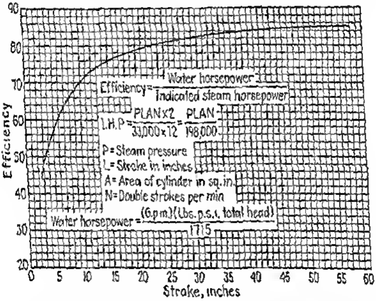

FIG. 27.—Steam-driven reciprocating pump mechanical efficiency.

The force developed on the steam end should be at least 50 percent greater than that on the water end to secure reliable operation, *i.e.*, $\frac{p_s}{p_w}\left(\frac{D_s}{D_w}\right)^2 = 1.5$, where p is the pressure, and D the cylinder diameter, and the subscripts s and w refer to the steam and water ends, respectively. If a factor of 94.5 percent is assumed for the slip and volume loss due to the rod, the flow from a double-acting pump is $Q = 0.00645D_w^2Ln = 0.0385D_w^2V$, the symbols being those given above with the addition that D_w is the diameter of the water cylinder in inches.

To prevent cavitation and consequent flow stoppage in the suction line, the **suction lift** (the vertical distance from the water surface to the top of the pump discharge-valve deck) must be kept within safe limits. Figure 30 issued by the Hydraulic Institute gives these values as a function of the water temperature. Curves T, N, and M are, respectively, the theoretical, normal, and maximum possible suction lifts at sea level. The horizontal distance between T and N represents the additional head required to prevent cavita-

Pump	Discharge Pressure
Ballast	35

Sanitary or flushing	85

[a] P_b is the boiler pressure, and C a constant that equals 65 if an economizer is used; 50, if it is not.

[b] The capacity of these pumps in gpm approximately equals

$$30 + \sqrt{(7.15)(\text{shp}) + 1{,}300},$$

where shp is the ship shaft horsepower.

tion. It includes an allowance for air in the water and the hydraulic losses usually found in a short suction line with one bend and a fluid velocity not greater than 3 fps. For water temperatures greater than 212 F the same differential of 12 ft between curves *T* and *N* must be maintained.

Basic speed curves for simplex, duplex, and triplex power pumps are given in Fig. 31, as issued by the Hydraulic Institute. The temperature and

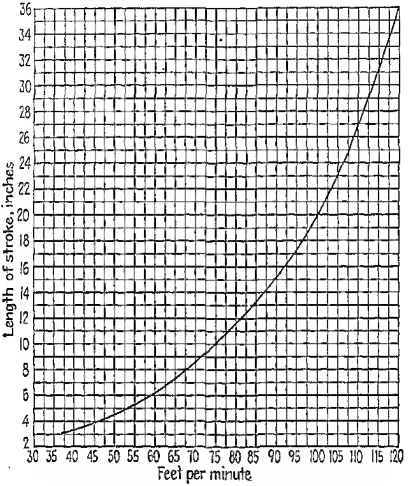

FIG. 28.—The Hydraulic Institute curve of basic speeds for simplex and duplex direct-acting steam pumps.

viscosity correction curve of Fig. 29 also applies to this figure. Figure 32 gives the approximate efficiency for pumps of this type, which is defined as the ratio of the water horsepower to the required horsepower input.

A relatively new type of power pump having a variable stroke is the Aldrich-Groff Powr-Savr, illustrated in Fig. 33, which is particularly suitable *for pressures over 250 psi at the discharge, as for boiler-feed pumps.* The pump is driven by a constant-speed motor, *F*, through herringbone reduction gearing from motor to crankshaft, *G*, which operates the connecting rods, *H*. The other end of each rod, *H*, is pivotally connected to links, *I*, by the con-

AIR AND GAS COMPRESSORS

BY

PAUL DISERENS

Bouché, "Kolbenverdichter," Springer.

Types of Compressors. For pressures below that of the atmosphere, many types of compressors are available. **Fans** (see p. 1668) are usually used for exhaust systems for handling foul air and shavings or other light material. **Jet blowers** (p. 1639) are also used, and for the low pressures occurring in condensers, piston and special centrifugal or impeller types are employed.

For compressing large quantities of air to pressures of 5 or 10 lb, and in some cases pressures as high as 100 lb and over, **centrifugal compressors** (turboblowers, p. 1656) are being increasingly used.

Piston compressors are built for pressures as low as 1 lb above atmospheric, and single cylinders are used with "single-stage" compression to pressures of 80 or 100 lb per sq in. gage. When **higher pressures** are desired, the compression is divided into stages, with intercoolers between the cylinders. Two-stage compressors are used for pressures from 80 or 100 to 500 lb, three-stage for pressures up to 1,200 lb (in small units up to 2,000 or 2,500 lb), and four-stage for pressures of 2,500 to 5,000 lb per sq in. or even higher. All these types of piston compressors may be driven by steam or internal-combustion engines, electric motors, or water wheels.

Specific Heat. The instantaneous specific heat at constant pressure of **dry air** is given by F. G. Swann as $0.24112 + 0.000009t$, and the specific heat of **water vapor** as $0.4423 + 0.00018t$, where t is the temperature, F. The specific heat of **moist air** with any degree of saturation may then be found by multiplying the weight of air by its specific heat and adding to this the product of the weight of water vapor and its specific heat and dividing the sum by the weight of the mixture. Table 3 is calculated on that basis.

For dry air at high temperatures, see p. 367.

Table 3. Specific Heats of Dry and Saturated Air

Temp, F	Specific heat of		Temp, F	Specific heat of	
	Dry air	Saturated air		Dry air	Saturated air
60	0.2417	0.244	85	0.2419	0.2474
65	0.2417	0.2447	90	0.2419	0.2486
70	0.2417	0.2452	95	0.2420	0.2498
75	0.2418	0.2458	100	0.2420	0.2512
80	0.2418	0.2466	105	0.2420	0.2526

The specific heat of air having any relative humidity may be found from Table 3 by interpolation. For example, for air of 40 percent relative humidity and at 80 F, the specific heat will be $0.2418 + 0.40 \times (0.2466 - 0.2418)$, or 0.2437.

The variation of the specific heat of air with pressure has been investigated by Holborn and Jakob (*Z. Ver. deut. Ing.*, 58, p. 1436). The mean specific heat at constant pressure for the temperature range 20 to 100 C (68 to 212 F) is given by the equation $10^4C_p = 2413 + 2.86p + 0.0005p^2 - 0.00001p^3$, where p is the pressure in kg per sq cm. Values of the specific heat of air at constant pressure C_p as determined by various observers are tabulated at the top of page 1637.

curve. The curve has two branches which approach more and more nearly two straight lines called the **asymptotes**. Each asymptote makes with the principal axis an angle whose tangent is b/a. The relations between e, a, and b are shown in Fig. 48: $b^2 = a^2(e^2 - 1)$, $ae = \sqrt{a^2 + b^2}$, $e^2 = 1 + (b/a)^2$. The semi-latus rectum, or ordinate at the focus, is $p = a(e^2 - 1) = b^2/a$.

Any section of a right circular cone made by a plane which cuts both nappes of the cone will be a hyperbola. (Compare also Fig. 3, p. 174.)

Equation of the Hyperbola, center as origin:

$$\frac{x^2}{a^2} - \frac{y^2}{b^2} = 1, \text{ or } y = \pm \frac{b}{a}\sqrt{x^2 - a^2}.$$

If $P = (x,y)$ is on the right-hand branch, $PF = ex - a$, $PF' = ex + a$. If P is on the left-hand branch, $PF = -ex + a$, $PF' = -ex - a$.

Equations of Hyperbola in Parametric Form. (1) $x = a \cosh u$, $y = b \sinh u$. (For tables of hyperbolic functions, see pp. 60 and 61.) Here u may be interpreted as A/ab, where A is the area shaded in Fig. 49.

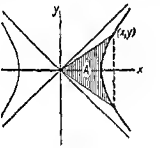

Fig. 49.

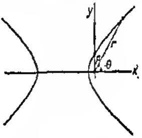

Fig. 50.

(2) $x = a \sec v$, $y = b \tan v$, where v is an auxiliary angle of no special geometric interest.

Polar Equation, referred to focus as origin, axes as in Fig. 50:

$$r = p/(1 - e \cos \theta).$$

Equation of the Tangent at (x_1,y_1): $b^2x_1x - a^2y_1y = a^2b^2$.

The line $y = mx + k$ will be a tangent if $k = \pm\sqrt{a^2m^2 - b^2}$. The tan-
